In order to validate the results obtained with different water models in computer simulations, the liquid-liquid transition in supercooled water has been studied also with very refined methods of calculation of the free energy already typically used for the analysis of the second order phase transitions. The free energy was considered as function of two order parameters: the density and also a bond orientational order parameter that indicates the degree of crystalline order to exclude the formation of ice upon cooling.

Recent interpretations of experiments and computer simulations start to consider liquid water as a mixture of the two competing states with different short range order HDL and LDL. With refined numerical analysis it is possible to evidence that water show a bimodal distribution of the two components. At ambient conditions the HDL component prevails but upon supercooling the LDL component appears and at low enough temperature starts to prevails. The liquid behaves similarly to a non ideal binary mixtures dominated by an interplay between energy and entropy. In this respect the critical point will be determined by an entropy driven unmixing process.

A number of recent experiments evidenced the presence of LDL/HDL states in agreement with the theoretical predictions.

A clear support to the two state model and the liquid-liquid transition derives also from the study of the dynamical behavior of supercooled water.

Dynamics of supercooled liquid water

If we want to study the dynamics of translational motion of the water molecules we have to consider the diffusion and the density fluctuations of the center of mass of the molecules that corresponds approximately to the position of the oxygen. Supercooled water show a dynamical behavior very similar to the other supercooled liquids but with a very important peculiarity related to the presence of the LDL/HDL components.

The self intermediate scattering function of the oxygen's obtained by computer simulation upon supercooling, shows a long time KWW decay characterized by the stretched exponential

$$F_s^{OO}(k, t) \approx e^{-(t/\tau)^\beta} \quad (18)$$

In a range of temperature below melting the relaxation time τ follows the MCT prediction of a power law divergence, Eq. (13). However at given pressure in a range of density by going down in temperature it is found a crossover to an Arrhenius behavior, by recalling Eq. (6) and that $\tau \sim \eta$

$$\tau(T) = \tau_0 e^{E_A/k_B T} \quad (19)$$

In Fig. 9 it is shown the data obtained in the simulation of supercooled water with the use of the TIP4P/2005 model. The data can be fitted with the MCT until a certain temperature then it appears a clear deviation and the remaining points follow an Arrhenius behavior.

According to the classification introduced above this crossover from a fragile (MCT type) to a strong (Arrhenius type) behavior can be interpreted by considering that HDL and LDL have a more fragile and a more strong character respectively.

A detailed analysis in all the range of the supercooled region shows that the fragile to strong crossover (FSC) takes place at the crossing of the Widom line as shown in the scheme in Fig. 10.

These phenomenologies were observed with quasi elastic neutron scattering and optical Kerr effect measurements.

Fig. 9 Relaxation time of water (in logarithmic scale) at the indicated density. The black points are the data from computer simulation with the TIP4P/2005 model, the MCT fit is obtained with Eq. (13) by assuming T_C as a fitting parameter, the Arrhenius fit is obtained with Eq. (19).

Conclusion

Supercooled liquids represents an important metastable state characterized by very peculiar connections between thermodynamics and dynamical properties. The microscopic processes that produce the slowing down of dynamics and the corresponding increase of viscosity in approaching the glassy state are widely studied with various techniques in experiment and in computer simulation. Supercooled liquids are in fact important for applications, developing technologies and development of new materials.

Abstract

This overview of glassy materials begins with production methods, highlighting how the homogeneity achieved, the creation of flat surfaces and the elimination of bubbles leads to their inherent transparency. The links between composition, structure and behavior are explained, leading on to an extended discussion of the main properties, ranging from mechanical and chemical durability through thermal, optical, diffusion and electrical characteristics. These properties are linked to common applications.

Key points

- What differentiates glasses from other materials?
- How are they made?
- What are their compositions and structures
- Their thermal, chemical and mechanical properties
- Their optical properties
- Diffusion and electrical behavior

Introduction

Glasses feature widely in everyday life and also in science. Their transparency and chemical durability, combined with ease of fabrication, ensure a role in windows, containers, table- and laboratory-ware; they are key components in optical instrumentation, for example, microscopes, cameras, telescopes and optical fibers. Some devices utilize specific interactions between light and glass, for example, lasers. Other applications use their electrical and magnetic behavior, strength, and thermal characteristics, including crystallization and phase separation. The range and flexibility of known glass compositions allow different properties to be independently tailored. Combining glasses with other materials or modifying their behavior by coating has extended their use further. Understanding glass structure and its consequences is also challenging the boundaries of condensed matter physics.

What is a glass?

Glasses have been defined as inorganic products of fusion cooled to a solid without crystallizing. This encapsulates key properties: glasses have a liquid-like structure, but cooling has caused a transition from liquid to solid behavior. It also implies features that are now disputed: organic glasses exist, and melting is not the only route for glass making. A characteristic implicit in the definition is that crystallization rates are low; this is often associated with high melt viscosities below the liquidus (T_L). Glasses differ from amorphous solids, in that they can be reheated to the liquid state; the latter crystallize on heating before melting (Doremus, 1994; Scholze, 1988; Uhlman and Kreidl, 1990; Varshneya, 1994; Zarzycki, 1991; Ossi, 2003).

How are glasses made?

Often glasses are made from solids by heating until fully melted, bubbles have dissipated, and the melt is homogeneous. Commercially, temperatures may reach 1600 °C and melting may take days. Laboratory melts need a few hours. Density separation of batch components, differential melting rates, contamination by the container, and volatilization losses can limit the glass quality. High melt viscosities limit diffusion and militate against homogeneity; mechanical or convection-driven stirring may be necessary. The oxidation state of any multivalent ions depends on the atmosphere around the batch during initial melting; subsequently, equilibrium with the furnace atmosphere is achieved only slowly. Rapid quenching may be needed, for example, roller quenching, splat cooling onto a rotating copper wheel, or fiber pulling.

Alternative production routes include: condensation of vapor phase reaction products on cold substrates; hydrolysis of organic derivatives of silicon (e.g., $\text{Si}(\text{OC}_2\text{H}_5)_4$) or other components to give a gel that is dried and sintered to a fully dense product; and extended grinding or applying pressure to crystals.

Glass structure

Short-range order

Glass structures have been studied by X-ray or neutron diffraction, various spectroscopic techniques, and computer modeling. Their short-range structure often mirrors that of corresponding crystalline compounds, particularly higher temperature phases. Zachariasen postulated that single-component glass-forming systems have cations with low coordination numbers (3 or 4) surrounded by bridging anions, each linking two coordination polyhedra at corners rather than edges. SiO_2 consists of a matrix of SiO_4 tetrahedra (Fig. 1) that defines its low thermal expansion coefficient (TEC), high viscosity at T_L , and high melting point. Other single-component glass-forming systems include GeO_2 , BeF_2 , B_2O_3 , and As_2O_3 .

Fig. 1 A schematic representation of the structure of vitreous silica. The tetrahedral SiO_4 units in silica are represented by triangular units.

A second component can extend glass formation, for example, to 58 mol% Na_2O in the $\text{Na}_2\text{O}-\text{SiO}_2$ system. Each oxygen added breaks one corner linkage in the network, creating two nonbridging oxygens (Fig. 2). Silicons are called “network formers” and sodiums, which enter interstices surrounded by bridging and nonbridging oxygens are termed “network modifiers.” A silicon linked to three bridging and one nonbridging oxygen is denoted by Q_3 ; the spread of Q_n species depends on composition and is generally narrow. Adding soda (Na_2O) increases the TEC and reduces viscosity by depolymerizing the network, while increasing density by filling interstices. Various cations adopt a network-forming role (e.g., Ge, P, Pb). The melt structure, being flexible, can accommodate many modifier ions despite different radii and preferred coordination, for example, Li^+ , K^+ , Rb^+ , Mg^{2+} , Ca^{2+} , Fe^{2+} . Intermediate ions (Al^{3+} , Fe^{3+}) can take either role in the structure. Some oxide combinations form glasses even though the components do not—the network-forming ion is called a “conditional” glass former, for example, Al in $\text{CaO}-\text{Al}_2\text{O}_3$ glasses. The oxygens can also be (partially) replaced by other anions, for example, F, S, N (Scholze, 1988).

Properties can often be modeled using expressions that are linear functions of composition and the viscosity of industrial glasses is usually calculated rather than measured. Anomalies occur if a cation changes role with composition (e.g., B coordination depends on alkali content); the TECs of $\text{M}_2\text{O}-\text{B}_2\text{O}_3$ glasses display a minimum with composition (the “boric oxide anomaly”), requiring a $[\text{B}_2\text{O}_3]^2$ term in composition models. Liquidus temperatures, which are discontinuous across phase boundaries, are best modeled using the underlying free energy functions. Components can also interact: Na_2O decreases network connectivity, while Al_2O_3 is a network former at low concentrations and, being oxygen deficient, removes nonbridging oxygens. If $\text{Na}_2\text{O}:\text{Al}_2\text{O}_3 = 1$, a highly connected, viscous system results; excess Na_2O or Al_2O_3 decreases viscosity, in the latter case because Al coordination changes from [4] (former) to [6] (modifier).

Medium-range order

Diffraction experiments give structural data in the form of radial distribution functions, representing the summed distribution of atoms with distance around all species present (Fig. 3); network-forming ions sit in remarkably regular sites but longer distance correlations are harder to resolve because of peak overlap. Extended X-ray absorption fine structure (EXAFS) experiments allow study of the environment of individual species and suggest that network modifiers also sit within polyhedra of notable regularity, that is, all cations optimize their local structure. Such distribution functions show that the network-forming polyhedra can also form extended structures, for example, vitreous B_2O_3 consists of BO_3 triangles, that form planar groupings, termed boroxol rings (B_3O_6),

Fig. 2 A schematic representation of the structure of an $\text{Na}_2\text{O}-\text{SiO}_2$ glass illustrating the break-up of the network by the introduction of nonbridging oxygens (linked to only one Si), and the sites taken by the sodium ions.

Fig. 3 An idealized radial distribution function for SiO_2 . The first four peaks give the distribution of nearest neighbor Os around Si, the Si-Si distribution, the O-O distribution, and the distribution of second nearest neighbor oxygens around Si. The peak areas give coordination numbers and the breadths indicate thermal and structural disorder. A random distribution would give a parabolic curve. Experimental curves show some ripple at low r caused by data termination errors. Many authors now plot correlation functions ($\pi r g(r)$) rather than r.d.f.s.

Fig. 4 A schematic representation of the modified random network model for an $\text{Na}_2\text{O-SiO}_2$ glass showing the tendency for modifier ions to segregate.

not found in B_2O_3 crystals. The modified random network model for alkali silicate glasses is based on segregation of network modifying atoms into layers surrounding SiO_2 -rich regions (Fig. 4). The diffraction patterns for many glasses have a relatively sharp low-angle first diffraction peak, consistent with extended ordering, as confirmed by modeling and electron microscopy. IR spectroscopy supports such structural models by accounting for the network vibrational modes. In Raman and Brillouin scattering experiments, glasses have, as a common feature, a boson peak at 100 cm^{-1} that provides additional insight into nanometer-scale inhomogeneities. Models incorporating medium-range order are distinct from older microcrystallite theories of glass, discounted by the lack of small angle X-ray or neutron scattering beyond that predicted from incipient random fluctuations in density. These conclusions underpin the thermodynamic modeling of glass properties based on contributions from components with appropriate compositions in defined proportions (Zarzycki, 1991).

Defects

Glasses can contain bonding and electronic defects induced by radiation or high temperatures. Their concentrations are low but they influence optical properties by introducing visible or ultraviolet (UV) absorptions and causing refractive index (r.i.) changes. Defects may involve unpaired electrons (*), e.g., the nonbridging oxygen hole center, $\equiv\text{Si}-\text{O}^*$; E' center, $\equiv\text{Si}^*$; peroxy radical, $\equiv\text{Si}_2-\text{O}-\text{O}^*$; or species such as Zr^{3+} , F_2^- . Some defects can be eliminated by optical or thermal bleaching, while others survive for years under normal conditions.

Nonsilicate glass-forming systems

Silicate glasses have three-dimensional (3D) network structures with intermediate ionic/covalent bonds. Alkali phosphate glasses have similar bonding but are often better described as chains (Ropp, 1992). Chalcogenide glasses are largely covalent and based on networks, sheets, chains, and rings. Hydrogen-bonded molecular glasses are common in organic systems (e.g., sugars), while some highly ionic or metallic systems adopt almost random close-packed structures. Various salts (nitrates, sulfates, acetates) also form glasses. Even crystals can show glassy behavior. Spin glasses may form in magnetic systems, based on disordered arrangements of unpaired electron spins, or molecules may have random orientations on a regular lattice as in KBr-KCN. Polymers usually consist of covalently bonded chains, which may have irregular monomer unit sequences or cross-link randomly along their lengths, giving glassy materials at low temperatures that cannot untangle into crystalline forms. In extreme cases, oxide glass melts have been described with two or more configurations that transform only slowly from one to the other or may coexist in equilibrium (Ropp, 1992).

Crystal growth and phase separation

Once a melt is cooled below T_L , crystal growth is possible. The driving force (difference in free energy between crystalline and liquid state) increases with undercooling and initially growth rates rise as temperature falls (Fig. 5). Subsequently kinetic factors, for example diffusion through the melt to the growing crystal and atomic rearrangement at the interface, limit growth. In stable glass-forming systems, growth rates may be only mm h^{-1} but may reach m s^{-1} in glassy metals. For large undercoolings the fastest growing phase is not necessarily the primary phase defined by the phase diagram; metastable phases also often form. Crystallization requires a nucleation step. Homogeneous nucleation is an intrinsic property. The free energy gain on producing a crystalline nucleus

Fig. 5 A schematic representation of the crystal growth and nucleation curves for a single phase precipitating from a glass-forming melt. In reality other phases may also appear at different temperatures with their own growth rate curves.

must balance the energy penalty of generating its surface. Surface effects dominate for small particles and so nuclei must exceed a critical size before they are viable. Small undercoolings require a large critical nucleus whose spontaneous formation is improbable, so melts can exist metastably for long periods just below T_L . At lower temperatures, the critical nucleus size decreases and nucleation rates rise rapidly to a maximum just above T_g , subsequently falling as kinetic factors dominate. Homogeneous nucleation is, however, rare. Nucleation starts more easily from pre-existing discontinuities, for example, “dirty” surfaces or container walls. Nucleation can be engineered by dissolving at high temperatures a component that becomes insoluble on cooling and precipitates (by homogeneous nucleation or phase separation). Examples include halides (NaF, CaF₂, CuCl), oxides (TiO₂, ZrO₂, P₂O₅), or metals (Ag, Au). If homogeneous nucleation rates are high, two-step heat treatment in the nucleation and growth regions can give a finely crystalline structure. The resulting “glass ceramics” are made by standard melting and forming technology but, once crystallized, can have enhanced properties, while lacking the porosity intrinsic to conventional ceramics. Glass ceramics can remain transparent if the crystals are smaller than the wavelength of light and r.i. differences are minimized (Bach, 1995; Lewis, 1989).

Phase separation

Phase separation is the chemical segregation of a melt into two liquids, driven by an associated reduction in free energy, for example, Na₂O–SiO₂ melts, with Na₂O < 20 mol%, separate into SiO₂ and sodium silicate; the SiO₂ structure is relatively intolerant to impurities. The minor phase may occur as droplets or a continuously connected phase, whose scale depends on heat treatment time and whose microstructure can be preserved by quenching. The initial step may involve homogeneous nucleation or spinodal decomposition (no energy barrier). Borosilicate glasses also phase separate; the connected phase can be removed by solution, allowing manufacture of finely porous SiO₂.

Glass formation

First, the flexibility of linkages in network systems results in only small energy differences between glassy and crystalline states (cf. the many SiO₂ polymorphs). This is a key thermodynamic factor in glass formation. Second, the network connectivity and bond strength cause the high melt viscosity and slow crystallization rates. Finally, the high melting temperatures destroy, by reaction or solution, foreign particles that might otherwise catalyze crystallization. Mathematical models, based on crystal growth and nucleation behavior, and their degree of overlap with temperature, can predict critical cooling rates for glass formation. They suggest that many systems, including some metal alloys, can form glasses. Cooling rates of 10⁶ °C s^{−1} may be needed, so heat transfer limits their production to thin artifacts, for example, ribbons or wires. New glass-forming systems have been identified, based on TeO₂, Al₂O₃, Ga₂O₃, ZrF₄, InF₃, by using faster quenching, smaller samples, and purer materials melted under clean conditions to eliminate nucleating agents. Glasses are often associated with eutectics where liquidus temperatures are low and the melts differ most in composition (and structure) from crystalline compounds. Adding more components can also improve glass-forming ability—the so-called “confusion” or “garbage-can” principle (Doremus, 1994; Uhlman and Kreidl, 1990; Varshneya, 1994; Babcock, 1977; Rawson, 1991).

Viscosity

Melt viscosities (η) typically follow the Vogel–Tammann–Fulcher equation (VTF) with temperature: $\log \eta = A + B/(T - T_0)$ where A, B, and T_0 are fitted constants. At the temperature where $\eta = 10^{12}$ Pa s^{−1}, deformation rates are slow, the material is effectively solid over short times ($\sim 10^2$ s), and this provides one definition of the “glass transition temperature, T_g .” By the strain point ($\eta = 10^{13.6}$ Pa s^{−1}), stress release takes hours. First-order thermodynamic properties such as volume are continuous through the glass transition, in contrast to phase changes such as crystallization, but second-order thermodynamic properties (specific heat (C_p) or TEC) are stepped (Fig. 6). T_g can therefore also be measured from C_p or length changes using a differential scanning calorimeter or

Fig. 6 An idealized graph of the specific heat of a glass as a function of temperature during a constant heating rate experiment and the length of a glass specimen as a function of temperature under similar heating conditions. There is a step in C_p at T_g and a change of slope (corresponding to a step in the TEC) in the specimen length.

a dilatometer, but the values depend on the heating rate used, since the transition is kinetically defined, and are not necessarily equal for different properties. Some have concluded that glass flows at room temperature, it being a liquid, and have perpetuated a myth that old windows are thicker at their base. Neither measurements nor calculations substantiate such conclusions, flow having become immeasurably slow. Where old panes are thicker at one edge, it is a manufacturing defect.

A glass artifact, cooled quickly, will solidify with large temperature gradients present; the differential contraction on reaching room temperature can induce significant stresses. These stresses depend on cooling rate, TEC, elastic properties, and thickness; bulk articles are therefore annealed, by equilibration above T_g , followed by slow cooling to the strain point. Angell has compared glass-forming systems using normalized plots of $\log \eta$ against T_g/T ; those displaying Arrhenius behavior most closely he termed “strong” glasses while those with large deviations he termed “fragile.” Fragility implies cooperative breakdown of the melt structure into increasingly small units above T_g . The VFT formalism predicts $\eta = \infty$ at $T - T_0$. Some studies have attached physical significance to T_0 , relating it to the temperature where extrapolation of experimental data predicts that the entropy of a glass becomes equal to that of the corresponding crystal, that is, the configurational entropy falls to zero, a concept underpinning the “Kauzmann paradox” (Varshneya, 1994).

Processing

High melt viscosities, along with gravity and surface tension, aid shaping as the melt cools. Sheet glass achieves optical flatness by gravity-driven flow, while floating on a molten tin bath with a 7 mm equilibrium thickness defined by surface tension and density. Optical fibers maintain their r.i. profiles during drawing. Containers and laboratory ware are blown and pressed by complex machinery to give the desired glass distribution. Strain rates may be high. A few glasses display non-Newtonian flow by structural alignment during forming (Cable and Parker, 1992).

Transformation range effects

Glass structure does not depend only on composition but also on thermal history; densities may vary by 1%. Fast quenching freezes in a structural state corresponding to equilibrium at a higher temperature than slow cooling. The effective quenched-in equilibrium temperature is called the “fictive temperature.” Control of cooling through the transformation range allows fine tuning of an optical glass r.i., and low cooling rates ensure the whole sample has the same thermal history (and minimum stress). Optical glass manufacturers recommend that their products should not be heated above $T_g = 150^\circ\text{C}$ because of potential property changes. Similar considerations apply to the processing of glass sheets for LCD displays. The electronic circuitry used to address individual pixels is printed at high temperatures in several layers; precise registry demands dimensional stability. A glass heated in the transformation range may, after an initial instantaneous change, relax exponentially to a new equilibrium state (Maxwell spring and dashpot model). Stress release rates can be measured and accurate data as $f(t, T)$ are needed for high-precision fabrication. Detailed analysis suggests a stretched exponential formulation: $S_t = S_0 \exp. (-[t/\tau]^n)$ where S_t is the stress at time t , S_0 the initial stress, and τ is proportional to viscosity, n ranges typically from 0.5 near T_g to 1. Many other properties behave similarly although not necessarily with the same constants for a given glass. Study of relaxation behavior and structural dynamics has given fruitful insights into the nature of the glass transition. At lower temperatures, bulk flow ceases but atoms can slide into new relative positions corresponding to different local energy minima, associated with the disordered structure. Such effects are manifest in internal friction experiments, for example, measurement of the damping of a pendulum suspended from a glass fiber under torsion. Damping involves transfer of mechanical energy to thermal energy and is observed down to room temperature in silicate glasses. Different mechanisms, termed α and β relaxations, dominate as temperature rises. These are attributed to mechanisms from modifier ion motion and relative movement of nonbridging oxygens, to motion of whole structural units.

A related phenomenon is semipermanent densification of v-SiO₂ at high pressures (GPa). Deformations of several percent do not fully relax on return to normal atmospheric conditions. Kinetic studies of relaxation suggest a low activation energy process, which is therefore not bond breakage; Raman spectroscopy confirms this. Early mercury-in-glass thermometers also displayed delayed elasticity. After calibration at 100°C , the mercury failed to return immediately to its 0°C calibration point on cooling. This relaxation behavior was minimized in mixed alkali glasses. Similar effects have been observed in rare-earth doped glasses; optical pumping into particular excited states, and the consequent energy transfer to the lattice, has excited structural changes that only recover at raised temperatures. The associated r.i. changes allow holographic image storage (Brawer, 1985).

Thermal properties

Specific heats are consistent with Dulong and Petit’s law near T_g but show a positive step at T_g , the size of which indicates the level of structural breakdown occurring. Thermal conductivities are lower than for equivalent crystalline phases and decrease with falling temperature, consistent with the short phonon mean free paths associated with structural disorder. At high temperatures, heat transport by photons becomes significant—glass is semitransparent in the near infrared allowing absorption and re-emission as a heat transport mechanism, termed radiation conductivity. Radiation conductivity varies as T^3 and is significant in commercial glass melting (Babcock, 1977).

Mechanical behavior

Glasses are brittle, with strengths dominated by their surface state. In microhardness tests, they exhibit limited flow under compression, attributed to densification and faulting. No flow occurs under tensile stress however; surface flaws remain atomically sharp at high loads and are effective stress raisers (stress at crack tip is enhanced by $(r/\rho)^{1/2}$ where r is crack length and ρ tip radius). Flaws are induced by impact, friction, adhering particles of different TEC, and devitrification. Strengths of several GPa in undamaged fibers can fall to <50 MPa. Water attack at flaw tips under stress causes static and dynamic fatigue, which is maximized in glasses of poor chemical durability; conversely, v-SiO₂ is unusually strong because of its excellent durability. The stress intensity factor, K_{Ic} , allows isolation of compositional factors by eliminating the effects of flaw size. Variations between glasses are small and related to bond strengths or atomic packing densities. Strengths are improved by protective coating or surface compressive stresses induced by rapid cooling or ion exchange, where large cations replace smaller cations. Many glass ceramics have enhanced strengths, the crystals impeding crack growth (Lewis, 1989).

Optical properties

Glasses are intrinsically transparent because they lack internal structure (e.g., grain boundaries) where r.i. changes would scatter light. Transparency also requires the absence of absorption mechanisms. UV photons can excite bonding electrons into empty molecular orbitals, limiting transparency. v-SiO₂ and phosphate glasses have strongly bound electrons and are transparent to <200 nm, but nonbridging oxygens, with their more weakly bound electrons, reduce transmission. IR photons can excite atomic vibrations and SiO₂ is opaque beyond 4.5 μ m; OH absorptions usually limit transmission near 3 μ m. Transmission can be extended by reducing the natural vibrational frequencies using heavier ions and weaker bonding. Fluoride glasses based on singly charged anions and heavy cations (Zr, La, In, Hf) will transmit to 7.5 μ m and chalcogenide glasses (based on S, Se, Te) can transmit to 20 μ m (France et al., 1989).

The UV and IR absorptions in glass are responsible for its r.i., n , and wavelength dispersion, v , as implicit in the semi-empirical fitting formula of Helmholtz–Ketteler: $n^2 - 1 = A + \sum_i c_i \lambda^2 / (\lambda_{0i}^2 - \lambda^2)$ with λ_{0i} = wavelength of absorption bands and c_i a weighting factor related to band strength. SiO₂ has a low n because its strong bonding gives short λ_{0i} values, whereas PbO-rich glasses have longer λ_{0i} , and correspondingly higher n and v values. The UV absorption is associated with the $6s \rightarrow 6p$ transition of the lone pair electrons in Pb²⁺. These weakly bonded, highly polarizable electrons also increase the second-order coefficient of optical nonlinearity (n_2). $d^2n/d\lambda^2 = 0$ near 1.5 μ m for SiO₂ because of the competing effects of UV and IR absorptions, minimizing materials-based signal dispersion in fibers.

Transition metal and rare-earth ions introduce weak absorptions, which are broader than in crystals because of the inherent structural disorder. Such species color glass. The matrix composition can strongly influence excited state lifetimes, and affects absorption and emission peak shapes. Halide and chalcogenide glasses are often preferred hosts because their low phonon energy lattices increase excited state lifetimes. Crystallization, where dopant ions segregate into the crystal phase, can offer similar advantages but with more tightly defined dopant ion environments. Both glassy and transparent glass–ceramic materials make efficient lasers (in fiber form for telecommunications).

Color can result from precipitated particles, for example, Au, Cu, and Ag color glass red or yellow and Cu(Cl,Br), Cd(S,Se), or PbTe give sharp absorption edges in the UV, visible, or IR, depending on their bandgap. If particles exceed 20 nm, light scattering can become excessive. The electronic energy levels of these precipitates are influenced by particle size via quantum confinement effects, giving rise to enhanced optical nonlinearities.

Such materials require dissolution of an appropriate compound at high temperatures that will precipitate on cooling. Metals are dissolved as ions, reduced to atoms on cooling by a redox process (e.g., $Au^+ + Ce^{3+} \rightarrow Au^0 + Ce^{4+}$), and subsequently agglomerate. Electron transfer can be catalyzed by UV photons. Thus, regions of high metallic particle concentrations, capable of nucleating bulk crystallization, can be engineered. The crystallized regions can display differential HF etching rates, and finely structured products for fluidics or replacement bones for the ear can be made (Bamford, 1977; Paul, 1990).

Glasses are rarely birefringent being intrinsically isotropic, but anisotropy can be induced temporarily by stress, or permanently by shearing melts with chain-like structures or showing phase separation, while cooling through T_g .

The Faraday effect involves rotation of the plane of polarization of a light beam by a magnetic field. Applications include optical devices requiring rapid switching or protection against back-reflected light. The plane of polarization is rotated in one sense by diamagnetic materials and in the reverse by paramagnetic materials. Large diamagnetic effects occur in PbO–Bi₂O₃–Ga₂O₃ glasses because of the polarizable Pb and Bi ions, while typical paramagnetic materials contain rare-earth ions with unpaired 4f electrons, for example, Tb³⁺, Pr³⁺, and Dy³⁺. The equivalent effect for electrical fields is named after Kerr.

Energetic photons can form point defects or re-arrange bonds, causing density and r.i. changes that may be used for laser writing; Bragg reflecting gratings, for telecoms signal demultiplexing or stress sensors, are written in Ge-doped SiO₂ optical fibers by two interfering beams from an excimer laser. Light-induced differential etching rates in chalcogenide glasses allow manufacture of photo-diffractive elements (Cable and Parker, 1992).

Diffusion and electrical behavior

SiO_2 has an open structure allowing solution of small molecules (e.g., He, H_2) and significant diffusion rates, even at 20°C . Modifier ions block the diffusion paths but, being weakly bonded, may themselves diffuse below T_g . Some surface modification technologies, for example, chemical toughening or planar waveguide manufacture, use this. At room temperature, most glasses are insulators but ion motion can cause significant AC dielectric loss; consequently glass ceramics are often preferred substrates in the electronics industry. Glasses become ionic conductors at higher temperatures ($\sim 100^\circ\text{C}$) for silicate glasses with significant modifier ion content; larger ions and higher charge reduce conductivity). The phenomenon of fast ion conduction, observed in some crystalline ceramics, also occurs in glasses (Varshneya, 1994).

The mixed alkali effect is a characteristic of ionic conduction and diffusion. Fig. 7 plots the conductivity of glasses containing Na and K against concentration; a pronounced minimum occurs where $\text{Na}:\text{K} = 50:50$, explained by the different sites the two ions occupy. Sodiums hop easily between equivalent sodium sites but mixed sites create an energy barrier. The loss of vibrational coupling between adjacent ions may also reduce coordinated hopping. The mixed alkali effect is most pronounced below T_g , the cation sites being unable to relax (Doremus, 1994).

Both crystalline and glassy semiconductors display valence and conduction bands, and a bandgap. Interband states exist even in undoped glasses however, particularly near the band edge. Chalcogenide glasses, based on S, Se, Te with, for example, Ge, Si, As, Sb, Ga, and glasses with high concentrations of transition metals in mixed valence states (e.g., V, Fe) can be semiconducting, electrons hopping between adjacent ions in different oxidation states in the latter case. Chalcogenide glasses have typical semiconductor characteristics, for example, photoconductivity and xerography; a-Si is a common component of solar cells. They also display switching behavior. Low voltages give small currents but higher voltages can induce crystalline filaments of higher conductivity. If crystallization is reversible, a memory switch results (Rawson, 1991).

Conclusion

Because of their unique properties, glassy materials are widely used as containers and in architecture, in instrumentation, telecommunications, clean water production and as biomaterials. They are infinitely recyclable and so can be produced sustainably. They can be manufactured with a zero carbon footprint and are widely used in energy generation as well as for energy saving.

Abstract

The presence of atomic-structural (topological) disorder, as in amorphous/glassy materials, has significant effects on the character and behavior of electron states, particularly in disordered semiconductors/insulators. All electron states in perfectly crystalline solids are spatially delocalized; such Bloch states, characterized by well-defined values of electron wavevectors, reflect the underlying crystal symmetries. However, structural disorder destroys the long-range atomic-translational symmetry of crystals, and hence the electron wavevector is no longer a unique characteristic of electron wavefunctions in amorphous/glassy materials. Moreover, the sharp features (van Hove singularities) appearing in the electronic density of states of crystalline materials are broadened out in amorphous/glassy solids, due to disorder. But the key difference in the characteristics of the electronic-structure behavior between crystals and amorphous/glassy materials is in the nature of the electronic wavefunction: in crystals, the (Bloch) electron wavefunctions are all spatially delocalized, whereas in amorphous/glassy semiconductors and insulators, the electronic wavefunctions are spatially localized, due to potential-energy disorder, at the edges of the valence and conduction bands, and also in the bandgap between valence and conduction bands where the localized electron states are associated with atomic-coordination defects.

Key points

- Electronic states in amorphous/glassy materials are very different from those in corresponding crystalline solids, due to the presence of atomic-structural (topological) disorder
- In crystals, electronic wavefunctions are characterized by well-defined values of electron wavevector, whereas in amorphous/glassy materials, electron wavevectors are much less well-defined due to the effects of structural disorder
- The electronic density of states (EDOS) as a function of energy is more featureless in amorphous/glassy materials than in corresponding crystals—sharp “van Hove singularity” features in the EDOS of crystalline materials are absent in the EDOS of amorphous/glassy solids
- Amorphous/glassy semiconductors/insulators contain spatially-localized electron states, arising from atomic topological disorder, at the top of the valence band (VB) and at the bottom of the conduction band (CB) in the EDOS, as well as in the bandgap between VB and CB, the latter being associated particularly with atomic-coordination defects, such as over-coordinated atomic configurations and under-coordinated geometries (“dangling bonds”)

Nomenclature

a	unit-cell parameter
C_i^α	chalcogen atom with atomic coordination i ($=1-3$) and electric charge α ($-, 0, +$)
$D(E)$	EDOS (per energy per volume) $= g(E)/V$
E	electron energy
E_g	bandgap energy
$g(E)$	electronic density of states (per energy) $= D(E) \times V$

[☆]Change History: November 2022. SR Elliott updated Fig. 6.

k	electron wave vector magnitude
$\mathbf{k}$	electron wavevector
$\mathbf{r}$	real-space position vector
S_E	constant-energy surface of electron states in $\mathbf{k}$ -space
$u_k(\mathbf{r})$	function having periodicity of crystal lattice (in Bloch function)
V	volume
V_1	intrasite electron interaction
V_2	intersite electron interaction
α	inverse localization length of envelope of a localized state
α_1	inverse localization length of island state within a localized state
$\delta(E)$	Dirac delta function (of energy)
$\nabla_k E$	gradient of electron energy with respect to wavevector
θ	bond angle
$\rho_e(\mathbf{r})$	electron charge density
$\psi(\mathbf{r})$	electron wavefunction

Introduction

In this article, the term “electronic structure” is taken to mean a description of the details of the solution, in its totality, of the Schrödinger equation for electrons in solids. Two quantities characterize the Schrödinger eigen-equation solution, namely the eigenvalue (or electron energy, E) and eigenvector (or electron wavefunction, $\psi(\mathbf{r})$).

In the simple case of electron states in perfect single-crystalline materials, that is, those considered in most textbooks on the electronic theory of solids (Elliott, 1998), the term electronic structure is often restricted to a description solely of the electronic energy since, for translationally periodic systems, the electronic states themselves always have the same character and generic functional form. The electronic wavefunction is always spatially extended throughout the volume of the crystalline sample, and has the functional form of the “Bloch” function, that is, a product of a spatially extended plane-wave state and a function, $u_k(\mathbf{r})$, having the periodicity of the underlying crystal lattice:

$$\psi_k(\mathbf{r}) = u_k(\mathbf{r})e^{i\mathbf{k}\cdot\mathbf{r}} \quad (1)$$

where $\mathbf{k}$ is the (quantized) wavevector of the plane-wave component and is used as a label for the eigenstate. (This is not the case for disordered systems, as will be seen.)

Thus, for perfect single crystals, the electronic structure, characteristic of a particular material, is taken to refer to either the four-dimensional (4D) quantity, the electronic band structure, $E(\mathbf{k})$, or its 2D derivative, the electronic density of states (EDOS), $g(E)$, where generally

$$g(E) = \sum_i \delta(E - E_i). \quad (2)$$

The EDOS in this representation is simply a sum of Dirac delta functions at all allowed, quantized electron-energy eigenvalues, E_i ; it is the number of electron states at a particular energy in unit energy interval, and $g(E)$, therefore, has the units of inverse energy. Alternatively, for a single crystal, the EDOS can be obtained as a surface integral in $\mathbf{k}$ -space over the Brillouin zone of a constant-energy surface S_E of the electronic band structure, that is,

$$D(E) = \frac{2}{(2\pi)^3} \int_{E(\mathbf{k})=\text{const}} \frac{dS_E}{\nabla_k E}. \quad (3)$$

Here, $D(E) = g(E)/V$, where V is the volume of the sample, and hence this form of the EDOS has units of inverse energy times volume.

One special feature of the EDOS of crystalline solids is the presence of van Hove singularities, that is, sharp features in the density of states corresponding to flat regions of the band structure, for which $\nabla_k E = 0$ (cf. Eq. 3), that is, regions where there are a large number of electron states with different $\mathbf{k}$ -values in a very small energy interval.

It will be seen that the introduction of disorder in a solid can have dramatic effects on the above simple picture of electron states in single-crystal materials.

Nature of disorder

The translational periodicity characteristic of perfect single crystals can be disrupted in a number of ways. Although, in a given disordered material, a glass for instance, several different types of disorder may occur together, nevertheless it is instructive to consider such possible forms of disorder separately. Perhaps, the simplest form is substitutional disorder in which a different type of atom is substituted for another in the crystalline lattice of the host material. The simplest example of substitutional disorder is the inclusion of one type of atom in the structure consisting entirely of another type, for example, the electrical dopants, n -type phosphorus or p -type boron, in crystalline silicon (Fig. 1a). A related substitutional defect is the so-called antisite defect, for

Fig. 1 Schematic illustration of different types of substitutional disorder associated with point defects in solid (crystalline) materials: (a) a phosphorus donor atom in crystalline silicon; (b) an antisite defect in a binary crystal, AB, the central B atom substituting for an A atom; and (c) an atomic vacancy (e.g., in crystalline silicon, showing four dangling-bond orbitals pointing into the vacancy).

example, in a binary crystalline compound, AB, where only heteropolar (A–B) bonding occurs in the completely ordered case. The replacement of an A atom, for example, by a B atom leads to the formation of homopolar (B–B in this case) nearest-neighbor bonds (Fig. 1b). A related defect is the atomic vacancy, where an atom is missing at a lattice-related site (Fig. 1c). This type of disorder involves point (or zero-dimensional) defects.

A somewhat related 2D defect is the so-called antiphase boundary in a binary crystal, AB, where an entire plane of atoms is missing (i.e., a stacking fault exists): in this case, like atoms face each other across the antiphase boundary (Fig. 2).

Another type of disorder prevalent in crystalline materials is positional disorder, characteristic of vibrational motion: atoms are instantaneously displaced randomly from their equilibrium, lattice-related crystallographic sites, according to a Gaussian (normal) distribution in the case of thermal vibrational disorder (Fig. 3). Positional disorder in crystals due to vibrational motion is dynamic in nature: the time-averaged atomic positions are simply the equilibrium, lattice-related sites. However, for the case of noncrystalline (e.g., amorphous or glassy) materials, the positional disorder is static in nature, that is, the equilibrium atomic positions do not correspond to a crystalline lattice.

What really distinguishes an amorphous material from its crystalline counterpart, however, is the presence of topological disorder (Elliott, 1990). This can involve, for example, the presence of noncrystalline ring orders in (covalent) network materials, even though the nearest-neighbor atomic coordination remains the same (Fig. 4), or for amorphous metals, the presence of a distribution of nearest-neighbor coordination numbers, rather than a single coordination polyhedron as in the corresponding crystal (e.g., 12-fold coordination in face-centered-cubic (fcc) crystals). In this case, the disorder is more profound, and there is no simple displacement relationship between noncrystalline and crystalline structures, as there is for positional disorder, for example.

The presence of topological disorder also permits the existence of other types of defective structures, unique to the amorphous phase and not found in the crystalline state. For instance, in materials with strongly directed covalent bonds, isolated dangling-bond (under-coordinated) coordination defects can occur instead of the clusters of dangling bonds that always occur at the site of atomic vacancies in crystals of such materials, for example, the four (unreconstructed) dangling bonds pointing into the vacancy in the tetrahedral crystalline material, c-Si (Fig. 1c). In addition, isolated homopolar-bond defects can occur in amorphous compound materials (where in the stoichiometric composition, only heteropolar bonds would otherwise be expected), instead of the clusters of homopolar-bond defects that exist around an antisite defect (Fig. 1b) or along an antiphase boundary (Fig. 2) in the corresponding crystalline materials.

Effects of disorder on the electronic structure

General aspects

In the case of a perfect crystal, the allowed values of the quantized electron wave vector, $\mathbf{k}$, are set by the periodicity of the lattice: for example, for a 1D crystal with a unit-cell parameter a , and with N atoms in the sample, there are correspondingly N discrete $\mathbf{k}$ -states, equally spread in $k(=|\mathbf{k}|)$ in the first Brillouin zone, that is, for the range of k -values $-\pi/a < k < \pi/a$. Each electron eigenvalue (energy) is associated with a particular $\mathbf{k}$ -value, which shows that the electronic band structure, $E(\mathbf{k})$, is a well-defined quantity (see Fig. 5).

Fig. 5 Schematic illustration of a one-dimensional electronic band structure for a 1D crystal (dashed line) and an amorphous solid (solid lines, illustrating the uncertainty in electron wave vector k for a given eigenenergy).

The presence of a single defect (or a surface) is sufficient to break the infinitely ranged translational invariance characteristic of ideal single crystals. In the case of a disordered material with no translational periodicity, there is no crystalline unit cell and hence the electron wavevector becomes an ill-defined quantity and no longer is useful as a label for electron states. Although at low electron energies corresponding to small k (the electron wavelength being long compared to characteristic atomic-structural distances, for example, the nearest-neighbor bond length), the uncertainty in k is rather small, it rapidly increases with increasing energy (Fig. 5). In other words, the electron wave function for a disordered material can no longer be expressed in terms of a single plane wave, characterized by one particular k -value, as in the case for Bloch states in single-crystalline materials (Eq. (1)). Instead, in a disordered material, electronic wave functions can be regarded as comprising an increasing number of Fourier components with increasing energy.

In the light of the above discussion, evidently the electronic band structure, $E(k)$, is not an appropriate description of electron states for disordered materials. However, since the electron energy remains a well-defined quantity, even in the presence of strong disorder, the EDOS (as defined as a sum of delta functions by Eq. (2), but not in terms of the band structure, Eq. (3)) remains a valid form of description for the electron states of disordered materials.

The electronic density of states

The effect of disorder on the EDOS is varied: some changes are striking; others are more subtle. Perhaps, the most striking effect of the loss of translational symmetry is in the destruction (broadening) of the van Hove singularities in the EDOS that are a signature of the presence of flat electron-energy surfaces in k -space, characteristic of crystals (see Fig. 6).

However, van Hove singularities apart, the EDOS of many amorphous materials is often similar to that of their crystalline counterparts (see Fig. 6 for the case of silicon). This is particularly true for covalently bonded semiconductors/insulators, where the similarity in the electronic structure arises from marked similarities in the short-range atomic structural order between the two phases. In the case of amorphous and crystalline silicon, for example, the short-range structural motif is the SiSi_4 tetrahedron in both cases: the average nearest-neighbor bond length and bond angle are practically the same, although the amorphous phase is characterized by having an $\sim \pm 10\%$ variation in bond angle from the average tetrahedral value, $\theta = 109^\circ 28'$. (The translational periodicity of the crystalline phase is destroyed in the amorphous material, not so much by this bond-angle disorder as by the disorder in dihedral angles, that is, the angle of twist between pairs of corner-sharing connected tetrahedra.)

The reason for the overall similarity in EDOS between amorphous and crystalline states, for example, of silicon, can be seen from a simple tight-binding description of the origin of the electron states, and the similarity in the short-range order in both cases. Only two types of local electronic interactions are assumed to be operative, namely a nearest-neighbor intersite interaction, V_2 , between orbitals emanating from pairs of nearest-neighbor atoms and forming common bonds, and an intrasite interaction, V_1 between orbitals emanating from the same atom (Fig. 7). In the case of silicon, for example, atomic s- and p-orbitals hybridize to give the sp^3 -hybrid basis orbitals. The intersite interaction, V_2 , is responsible for a gap of magnitude $2V_2$ occurring between occupied and unoccupied electron states (i.e., the bonding–antibonding splitting). The intrasite interaction, V_1 , in this model, is responsible for the broadening of bonding and antibonding levels into, respectively, the valence and conduction bands, each of width $4V_1$ (Fig. 7), since it couples orbitals together in such a way that, together with the intersite interaction, an electron may hop from any given orbital on one atom to any other orbital on any other atom, thereby becoming delocalized (extended) throughout the sample volume. It should be noted that both V_1 and V_2 are negative quantities. In this model, a bandgap occurs between filled valence and empty conduction bands as long as the bonding–antibonding splitting is sufficiently large to overcome the opposing effect of the band broadening, that is, for

Fig. 6 Computed EDOS curves for: (a) a 2,097,172-atom model of diamond-cubic crystalline Si calculated using a tight-binding procedure; (b) two 512-atom models of amorphous Si, one generated by a reverse-Monte Carlo (RMC) method, the other by use of a machine-learned Gaussian Approximation Potential (GAP) used in an MD simulation. From Panel (a) Deringer VL, Bernstein N, Csányi G, Ben Mahmoud C, Ceriotti M, Wilson M, Drabold DA and Elliott SR (2021) Origins of structural and electronic transitions in disordered silicon. *Nature* 589: 59. Panel (b) Cliffe MJ, Bartók AP, Kerber RN, Grey CP, Csányi G and Goodwin, AL (2017) Structural simplicity as a restraint on the structure of amorphous silicon. *Physical Review B*, 95: 224108. Panel (c) Deringer VL, Bernstein N, Bartok AP, Cliffe MJ, Kerber RN, Marbella LE, Grey CP, Elliott SR and Csányi G (2018) Realistic atomistic structure of amorphous silicon from machine-learning-driven molecular dynamics. *Journal of Physical Chemistry Letters*, 9: 2879.

$$|V_2| > 2|V_1| \quad (4)$$

and the bandgap, therefore, has the value

$$E_g = 2|V_2 - 2V_1| \quad (5)$$

Since the average nearest-neighbor bond lengths and angles in amorphous and crystalline silicon are very similar, the magnitude of the electron-hopping interactions V_1 and V_2 are also expected to be very similar, and hence, for example, the width and shape of the valence band, and the magnitude of the bandgap between valence and conduction bands, is expected to be very similar for the two phases (see Fig. 6 for the case of Si).

Fig. 7 Illustration of the origin of the bandgap between valence and conduction bands for a tetrahedrally coordinated material, such as silicon. The successive sections show the atomic s - and p -levels, the sp^3 -hybrid level, the bonding-antibonding splitting resulting from the intersite electron interaction, V_2 , and the formation of bands resulting from the intrasite interaction, V_1 . The origins of the interactions V_1 and V_2 are shown in the inset.

Fig. 8 The density of states for the (lower-energy) valence-band tail calculated for a 10,000-atom model of amorphous silicon, showing the computed position of the LD transition energy ("mobility edge"). Visualizations of three representative spatially-localized electron eigenstates are also shown: a highly localized near-mid-gap state associated with a dangling bond; a localized tail state; and a critical state at the LD transition energy, each showing constituent island states, the number of which increase on approaching the LD transition. From Ludlam JJ, Taraskin SN, Elliott SR and Drabold DA (2005) Universal features of localized eigenstates in disordered systems. *Journal of Physics: Condensed Matter*, 17: L321

However, subtle changes in the EDOS can be caused by disorder. Since the bandwidth in this tight-binding picture is governed by the intrasite interaction, V_1 , and this interaction (as well as the degree of orbital hybridization) depends on the angle, θ , between (hybrid) orbitals at a site (Fig. 7), the fluctuations in θ will lead correspondingly to variations in the bandwidth, that is, a tailing of states at the band edges into the gap region (see Fig. 8). It appears, on the basis of experimental data, that these band tails in amorphous semiconductors generally have an exponential energy dependence:

$$g(E) = \frac{N_0}{E_0} \exp(E/E_0) \quad (6)$$

where N_0 is the total number of tail states, and E_0 is the energy decay parameter.

Substitutional disorder, for example, phosphorus donor dopants in silicon, that is, Si:P (Fig. 1a), also gives rise to electron states lying outside the bands of the perfect crystal; in the case of Si:P, these are donor levels just below the conduction-band edge. (Acceptor states associated with substitutional acceptors, for example, boron in silicon, Si:B, correspondingly lie just above the valence-band edge.) Substitutional defects comprising atoms having a greater electronegativity difference with the atoms in the host material correspondingly give rise to electron states lying deeper within the bandgap.

Although relatively small levels of disorder, for example, bond-angle deviations in covalent amorphous semiconductors, produce relatively small changes in the EDOS, that is, moderate band tailing into the bandgap, larger degrees of disorder can cause correspondingly larger changes in the EDOS. For instance, electron states associated with gross instances of disorder (e.g., coordination defects such as dangling bonds in amorphous network materials) have energy levels deeper in the bandgap than the bond-angle-fluctuation-induced band tails. The reason why (singly occupied) dangling-bond orbitals should have an electron energy lying near midgap in the case of a-Si can be seen from the simple tight-binding hybrid-orbital picture illustrated in Fig. 7: the dangling-bond orbital is a nonbonding state and hence should lie at the level corresponding to that of the sp^3 -hybrids (i.e., at midgap in this model). Such singly occupied, electrically neutral dangling-bond defects in silicon can be represented by the symbol Si_3^0 , where the subscript denotes the coordination number at the defect, and the superscript denotes the electrical charge state of the defect. Such Si_3^0 defects are electron-spin resonance (ESR) active because of the unpaired electron spin in the dangling-bond orbital.

Not all dangling-bond defects in amorphous semiconductors are paramagnetic, as they are in a-Si or a-Ge, however. In chalcogenide glasses, which contain the chalcogen (C) elements, S, Se, or Te, alloyed with neighboring elements (e.g., As, Ge, Sb, and B), bond reconstruction can make electron pairing at dangling-bond defects energetically favorable. An electron, transferred between two C_1^0 paramagnetic (Mott et al., 1975) chalcogen dangling-bond defects to create a C_1^+ , C_1^- defect pair, can be energetically stabilized by the formation of a dative bond between the empty p -orbital on C_1^+ and the filled nonbonding, lone-pair p - π orbital on a neighboring, normally bonded chalcogen (i.e., C_2^0), thereby forming an over-coordinated defect, C_3^+ , with the overall defect reaction being

The so-called valence-alternation pair (VAP) of defects, C_3^+ , C_1^- , is spin-paired and hence diamagnetic, and has energy levels closer to the band edges than the near mid-gap position of C_1^0 .

The electronic wavefunction

Disorder in a material can cause a qualitative change in the nature of the electron wavefunctions compared with the Bloch form (Eq. (1)) characteristic of perfectly crystalline solids. Instead of all wavefunctions being spatially extended (delocalized) as in the case of single crystals, the presence of disorder can cause some electron states instead to become spatially localized: (Kramer and MacKinnon, 1993) the envelope of the magnitude of the wavefunction then decays exponentially with distance away from the center of localization (or the site of maximum magnitude of the electron charge density, $\rho_e(r)$, or $|\psi(r)|^2$) as

$$\psi(r) = Ae^{-\alpha r} \quad (8)$$

where α^{-1} is the localization length.

An isolated substitutional impurity, for example, a P donor in c-Si (Fig. 1a), also shows clearly the disorder-induced localized nature of the associated electron wave function: the isolated donor state can be represented reasonably accurately by a 1s-like hydrogenic orbital having an exponential envelope, the extra donor electron being bound to the positively charged P^+ donor atom by the Coulomb interaction, screened by the dielectric constant of the Si host, resulting in the effective Bohr radius of the electron orbit (equivalent to the localization length) being several tens of unit-cell lengths in size.

The isolated dangling-bond electron state lying near mid-gap in topologically disordered amorphous semiconductors is more strongly exponentially localized, with the localization length being comparable to the nearest-neighbor bond length, $\alpha^{-1} \cong r_1$. It is generally true that, the deeper the energy level of an electron state in the bandgap, away from the valence-or conduction-band edges, the stronger the degree of spatial localization (i.e., the smaller the value of α^{-1}) of the associated electron wave function.

A remarkable feature of the nature of electron states in disordered materials, such as amorphous solids, is that there are critical energies in the tails of the bands, at which the character of the eigenstates changes from being spatially extended (but non-Bloch-like, and having a dispersion of k -values), for states nearer the band center, to being spatially (exponentially) localized, for states nearer the gap. The localization length, α^{-1} , of the envelope of the localized states diverges at the localization-delocalization (LD) transition. Fig. 8 shows this LD transition energy, sometimes called the (electron) mobility edge, because the electron transport changes there from being high-mobility diffusive for extended states to being low mobility involving thermal hopping for localized states, calculated for a structural model of a-Si with a realistic tight-binding electron-interaction Hamiltonian. Also shown in this figure are visualizations of the computed localized electron wavefunction for different representative energies in the gap and the band tail. A dangling-bond state deep in the bandgap is very strongly localized at a coordination defect, the localized wavefunction consisting of a single region of charge density having an exponential envelope. However, localized electron states in the band tail, especially with energies approaching the LD transition, do not consist of single uniform regions of charge density with ever-increasing localization length, α^{-1} . Instead, discrete “islands” of charge density occur within the overall exponential envelope of the localized wave function; these individual islands are also exponentially localized, but their localization length, α_i^{-1} , increases only very gradually, and the number of islands also increases significantly, as their energy moves toward the LD transition. The electron eigenstate at the LD transition itself is a multifractal state consisting of a dense collection of the individual island states (see Fig. 8).

Conclusion

The effects of disorder on electron states in solids are fourfold: (1) the electron wavevector is no longer a good quantum number; (2) sharp features in the density of states are destroyed; (3) bands broaden, creating band tails having an exponential energy dependence; and (4) electron states in band tails and in the bandgap region, lying below a critical energy and corresponding to very disordered sites, are exponentially spatially localized.

Abstract

When a system, composed of some substance, is displaced from equilibrium, the forces which were maintaining equilibrium will bring the system back toward equilibrium. Because of the mass of the substance, the system will overshoot equilibrium, then have to return, and subsequently the system will oscillate about equilibrium. This is the essence of acoustics, and it applies to virtually everything, from molecules to galaxies. In acoustic experiments, measurements of acoustic motion and damping, over a wide range of conditions, can be made to high precision and accuracy, and significant information may be obtained about the thermodynamics and interatomic forces involved in condensed matter physics.

Key points

- Provide a detailed theoretical basis for the physics of acoustics
- Discuss precise and accurate experimental acoustic measurement techniques
- Review acoustic measurements on basic liquids and solids
- Review acoustic measurements on exotic liquids and solids
- Present some special applications of acoustics

Introduction

For many materials, acoustic measurements provide a crucial probe of important and fundamental physics of the material. In the case of solids, acoustic data determine derivatives of the free energy with respect to atomic positions (the elastic constants), and can provide information about the environment for electronic phenomena, including piezoelectric, electron-phonon and magnetic effects, and about energy dissipation pathways. Involving tensor quantities, acoustics can probe anisotropic properties of crystals. For both solids and liquids, the measurement of acoustic properties, when taken as functions of temperature, pressure, etc., can be related to other fundamental thermodynamic quantities such as the equation of state, specific heat, Debye temperature and the Gruneisen parameter, and they can be used to check theoretical models. Acoustic measurements are a sensitive probe of first and

[☆]Change History: July 2022. JD Maynard updated the chapter.

second order phase transitions and critical phenomena, including structural transitions in solids, the superconducting transition and the superfluid transition. The application of acoustics in condensed matter physics is a vast field, so only some topics can be covered here. Fortunately, there exist comprehensive accounts in books and review articles; such accounts include the topics of experimental methods (Truell et al., 1969; Goodwin and Trusler, 2003; Leisure, 2017), acoustics for liquids (Levy et al., 2001a), for solids (Levy et al., 2001b; Luthi, 2005; Leisure, 2017), for piezoelectrics (Cady, 1946; Rosen et al., 1992; Yang, 2018), for superfluids (Rudnick, 1970; Kojima, 2001) and for superconductors (Schrieffer, 1964; Levy, 1992), and for acoustic studies of phase transitions and critical phenomena (Ahlers, 1980; Leisure, 2017; Luthi, 2005; Rudnick, 1970, 1978) and damping mechanisms in solids (Bhatia, 1967; Leisure, 2017). Before discussing the principles of acoustics for condensed matter, it would be worthwhile to present some fundamentals of acoustic measurements, because this would elucidate the connections between acoustic theory and experiment.

Most of the early acoustic measurements on materials were made using the time-of-flight of pulses. For solid crystals, this could require re-orienting samples and re-mounting transducers, but analyzing the results to obtain material properties required relatively little computation. However, with the advent of powerful computers, more information can be obtained with a single, simpler measurement. In this case, acoustic resonators are most appropriate, for the following reasons: In introductory physics, it is shown that for a mass on a spring with damping, driven by an oscillating force, the amplitude of the motion of the mass as a function of frequency is a tuning curve, with a peak at the resonance frequency and a defined width. The quality factor Q of the resonance is the resonance frequency divided by the width. Assuming the mass is known, the spring constant may be determined from the resonance frequency and the damping may be determined from the Q . Furthermore, if the system is driven not by an oscillating force on the mass, but by an oscillating displacement at the end of the spring, then at resonance the amplitude of the mass motion is Q times larger than the amplitude of the drive. Thus using a resonator to make measurements has two advantages: first, information is obtained from frequency, which the easiest quantity to measure accurately, and second, one may take advantage of a natural, noise-free amplifier with a gain equal to the Q . Acoustic resonators may be fashioned for condensed matter samples ranging in three-dimensional size from a few hundred microns to meters, as well as samples in the form of thin films or filaments.

In an acoustic resonance measurement, the resonator is designed to minimize damping and avoid any extraneous perturbations of the resonance frequency (or frequencies). One or more tuning curves are recorded and fitted so as to obtain precise resonance frequencies and quality factors. These, along with information about the resonator, are entered into a computer program which then determines the material properties. In the next sections, the theories for fluids and solids will include discussion of the connection between material properties and acoustic resonances and quality factors.

Basic acoustic theory

A condensed matter material is taken to be a large collection of atoms, and within the collection an arbitrary volume V inside a closed surface $\mathcal{A}$ is considered. It is assumed that the volume is just large enough so that a sum of a quantity over the atoms inside may be replaced by an integral of a field over the volume. The motion of the volume is taken to be that of its center-of-mass; the motion of the atoms inside the volume about the center-of-mass is accounted for with thermodynamics. The volume may be defined for only a short time, from t to $t + dt$, sufficient to determine equations governing the dynamics of the fields.

The force acting on the volume is due to the interaction of the atoms just outside the surface with the atoms just inside the surface. For a patch of area $d\mathcal{A}$ with a unit outward normal $\hat{n}$, the force would be proportional to $d\mathcal{A}$ and in a direction which may be written as a rotation of $\hat{n}$: $d\vec{F} = \vec{\sigma} \cdot \hat{n} d\mathcal{A}$, where $\vec{\sigma} = \{\sigma_{ij}\}$ (with $i, j = 1, 2, 3$ indexing Cartesian coordinate axes, having unit vectors $\hat{x}_i$) is referred to as the stress tensor. The force per unit area $d\vec{F}/d\mathcal{A} = \vec{\sigma} \cdot \hat{n}$ is called the traction.

Net stresses occur when the relative distance between atoms change, which may be determined from a displacement field $\vec{\Psi}(\vec{r}, t)$, defined so that a point in the material originally at $\vec{r}$ is displaced to $\vec{r} + \vec{\Psi}(\vec{r}, t)$. For a nearby point $\vec{r} + d\vec{r}$, its displaced position is $\vec{r} + d\vec{r} + \vec{\Psi}(\vec{r} + d\vec{r}, t)$. The change in the distance between the two points is found from $\vec{\Psi}(\vec{r} + d\vec{r}, t) - \vec{\Psi}(\vec{r}, t) = \hat{x}_i (\partial \Psi_i / \partial x_j) dx_j$ (using the convention that indices repeated in a term indicate summing over those indices). Noting that rotations do not change distances, the change in displacements between nearby points is expressed with a tensor which is symmetric (thereby excluding rotations): $\hat{x}_i e_{ij} dx_j$, where $e_{ij}(\vec{r}, t) = (1/2)(\partial \Psi_i / \partial x_j + \partial \Psi_j / \partial x_i)$.

Other fields include the mass density ρ , the velocity $\vec{\mathcal{U}} = \partial \vec{\Psi} / \partial t$, the entropy per unit mass S , and temperature T (not necessarily constant). All fields may be functions of position $\vec{r}$ and time t . Other quantities usually assumed to be constants include the shear viscosity η , the bulk viscosity ζ and the thermal conductivity κ . Defining a streaming derivative as $D/Dt = \partial/\partial t + \vec{\mathcal{U}} \cdot \vec{\nabla}$, the constitutive equations (Huang, 1987) are conservation of mass, Newton's law and conservation of energy:

$$\frac{D\rho}{Dt} + \rho \vec{\nabla} \cdot \vec{\mathcal{U}} = 0 \quad (1)$$

$$\rho \frac{D\vec{\mathcal{U}}}{Dt} = \vec{\nabla} \cdot \vec{\sigma} + \eta \nabla^2 \vec{\mathcal{U}} + \left(\frac{1}{3}\eta + \zeta\right) \vec{\nabla} (\vec{\nabla} \cdot \vec{\mathcal{U}}) \quad (2)$$

$$\rho \frac{DS}{Dt} = \frac{2\eta}{T} \left[\frac{\partial e_{ij}}{\partial t} - \frac{1}{3} (\vec{\nabla} \cdot \vec{\mathcal{U}}) \delta_{ij} \right]^2 + \frac{\zeta}{T} (\vec{\nabla} \cdot \vec{\mathcal{U}})^2 + \frac{1}{T} \vec{\nabla} \cdot (\kappa \vec{\nabla} T) \quad (3)$$

where δ_{ij} is the Kronecker delta. Counting the three components of Newton's law as three independent equations, there are five constitutive equations. The fields $\vec{\mathcal{U}}$ and e_{ij} are determined from the displacement field $\vec{\Psi}$, and the stress tensor σ_{ij} may be

determined from e_{ij} . In thermodynamics, the temperature T , in theory, may be written as a function of the entropy S and the mass density ρ . Thus there are five independent fields: ρ , S and the three components of the displacement field $\vec{\Psi}$, and these are governed by the five constitutive equations.

For piezoelectric and piezomagnetic materials, electric and magnetic fields must be included, along with more constitutive equations. However, it can be shown that magnetic effects are smaller than electric effects by a factor given by the speed of sound divided by the speed of light (Auld, 1990), which has a maximum value of $\sim 10^{-5}$. Thus piezomagnetic effects are small and will not be considered here. For piezoelectric effects, it is sufficient to add just one field, the electric potential Φ , which gives the electric field $\vec{E} = -\nabla\Phi$, and from $\vec{E}$ the electric displacement $\vec{D}$ may be determined. Noting that piezoelectric materials cannot have free charges (otherwise their displacement would cancel any piezoelectric field), then a Maxwell equation gives $\vec{\nabla} \cdot \vec{D} = 0$. Thus for piezoelectrics, there is one additional field, Φ , and one additional constitutive equation.

For acoustics, it is assumed that a material undergoes only small deviations from equilibrium. Applying just this to the constitutive equations still results in mathematically difficult and nonlinear equations, so some further assumptions may be made to obtain basic results. First, nonlinear acoustics is an extensive subject on its own, so only first order approximations will be treated here. Second, effects of viscosity and thermal conductivity are small and may be treated perturbatively after basic acoustic equations are solved, so initially η , ζ and κ are set to zero. Finally, it is assumed that in equilibrium, all fields are constant in time and space.

The assumptions above have some immediate consequences. It is assumed that in equilibrium, $\vec{\mathcal{U}} = 0$, so that $\vec{\mathcal{U}}$ itself is small. Since only small deviations depend on position, then $\vec{\nabla}$ operates only on small quantities. Thus, in the streaming derivative, $\vec{\mathcal{U}} \cdot \vec{\nabla}$ is second order, and can be dropped, so that $D/Dt \simeq \partial/\partial t$. With this, and dropping viscosity and thermal conductivity, Eq. (3) becomes $\partial S/\partial t = 0$, so that for basic acoustics, entropy is constant.

In the next section, the acoustic theory for fluids will be presented, followed by a section on acoustic theory for solids and piezoelectrics.

Acoustic theory for fluids

Fluids, by definition, cannot support shear stress, so that $\sigma_{ij} = -P\delta_{ij}$, where $P(\vec{r}, t)$ is the pressure field in the fluid. For small deviations from equilibrium, $\rho = \bar{\rho} + \rho'(\vec{r}, t)$ and $P = \bar{P} + P'(\vec{r}, t)$, where $\bar{\rho}$ and $\bar{P}$ are the constant, equilibrium values of mass density and pressure. Eqs. (1) and (2) become

$$\frac{\partial \rho'}{\partial t} = -\bar{\rho} \vec{\nabla} \cdot \vec{\mathcal{U}} \quad (4)$$

$$\bar{\rho} \frac{\partial \vec{\mathcal{U}}}{\partial t} = -\vec{\nabla} P' \quad (5)$$

Since entropy is constant, thermodynamic derivatives at constant entropy S can be used to relate small quantities (also defining a quantity c_s): $P' = (\partial P/\partial \rho)_S \rho' = c_s^2 \rho'$; $c_s^2 = (\partial P/\partial \rho)_S = \gamma/\mathcal{K}_T$ where γ is the ratio of the specific heat at constant pressure to the specific heat at constant volume, c_p/c_v , and $\mathcal{K}_T = (1/\rho)(\partial \rho/\partial P)_T$ is the isothermal compressibility. Taking two time derivatives of $P' = c_s^2 \rho'$ and using Eqs. (4) and (5), one obtains

$$\frac{\partial^2 P'}{\partial t^2} = c_s^2 \frac{\partial}{\partial t} \left[\frac{\partial \rho'}{\partial t} \right] = c_s^2 \frac{\partial}{\partial t} \left[-\bar{\rho} \vec{\nabla} \cdot \vec{\mathcal{U}} \right] = c_s^2 \vec{\nabla} \cdot \left[-\bar{\rho} \frac{\partial \vec{\mathcal{U}}}{\partial t} \right] = c_s^2 \vec{\nabla} \cdot [\vec{\nabla} P'] = c_s^2 \nabla^2 P' \quad (6)$$

This is the wave equation with a speed of sound $c_s = \sqrt{(\partial P/\partial \rho)_S}$. A sound wave in a fluid also has a temperature oscillation, with an amplitude relative to the pressure amplitude given by $T'_0 = P'_0(\gamma - 1)/\bar{\rho} c_s^2 \beta_p$, where β_p is the thermal expansion coefficient.

At this point, acoustic energy dissipation (losses) due to viscous and thermal conductivity effects may be addressed. As discussed earlier, the quality factor Q accounts for damping in a resonance, and may be determined experimentally as the resonance frequency f divided by the width of the resonance. The Q may also be expressed with a theoretical formula; in this case the Q is $2\pi f$ times the acoustic energy stored in the resonator divided by the rate at which energy is dissipated. The energy stored may be expressed as the kinetic energy plus the potential energy of the acoustic field, expressed in terms of the first order fields found for the resonator. The rate of energy dissipated is equal to the rate at which heat is generated, which is just the temperature T times $\partial S/\partial t$, which is given by Eq. (3). The theoretical formula for the quality factor is found to be

$$Q = \frac{\bar{\rho} c_s^2}{4\pi^2 f^2} \left[\left(\frac{4}{3} \eta + \zeta \right) + \frac{\kappa}{\gamma c_v} (\gamma - 1) \right]^{-1} \quad (7)$$

The effects of bulk viscosity are usually small and will not be considered here. Eq. (7) is for dissipation only within the volume of fluid; there may be other losses at the interface between the fluid and the walls of the resonator. In particular, shear viscous loss as fluid oscillates back and forth next to a wall usually dominates the dissipation. However, this loss may be completely eliminated with the use of a spherical resonator (Goodwin and Trusler, 2003; Leonard, 1946). In such a resonator, some of the modes involve only radial motion of the fluid, so that there is no motion of the fluid parallel to the wall, and thus there are no wall shear viscous losses. Another advantage of the spherical resonator is that, for a fixed volume, deviations from perfect sphericity have only second order effects on the resonance frequencies. Yet another advantage is that an electrically conducting spherical resonator can also measure microwave resonances, which may be used to calibrate the sphere; in this case, measured sound speeds may be referenced

to the speed of light, which is a defined constant. The only intrinsic limitation is that the walls of the resonator usually have a relatively high heat capacity, and remain at constant temperature. In this case, the temperature oscillations in the fluid result in thermal conductivity losses. In any case, the use of different resonators and/or different modes of resonance can enable an accurate determination of c_s , η and κ from measured resonance frequencies and quality factors.

Usually acoustic resonance in fluids corresponds to fitting an integral number of half-wavelengths into a relevant linear dimension. With the wavelength being the speed of sound divided by the frequency, then a study at a low frequency could require a large resonator. This inconvenience can be avoided with the use of a Helmholtz resonator, which is a fluid version of a mass on a spring. This resonator consists of a volume of fluid inside a rigid-walled vessel which opens through a neck to a large (assumed infinite) reservoir of fluid. The volume acts as a spring, the fluid in the neck acts as a mass, and the shear viscous losses at the walls of the neck act as damping. The resonance frequency may be low without requiring that the resonator size be on the order of a wavelength. However, a drawback is that it is difficult to accurately account for the radiation of sound out of the neck into a reservoir which is not infinite. This drawback is eliminated with the double Helmholtz resonator, for which the neck connects two (usually identical) volumes; there is no opening out to a reservoir.

Acoustic theory for solids and piezoelectrics

Before discussing acoustic theory for solids and piezoelectrics, it would be worthwhile to introduce some details about resonance measurements for solids, particularly for a technique referred to as resonant ultrasound spectroscopy (RUS) (Maynard, 1996; Migliori and Sarrao, 1997; Leisure, 2017). A RUS apparatus measures resonance frequencies and quality factors, and this is typically done by contacting the sample with two transducers, a drive and a receiver; the drive provides an oscillating force, and as the drive frequency is swept, the receiver records a tuning curve when the frequency passes through a resonance of the sample. For a sample of solid material, the acoustic resonances depend on the shape and boundary conditions of the sample. It is usually assumed that the sample may be supported in such a manner that the boundaries (surfaces) of the sample are virtually stress free (i.e. the traction at all points on the sample surfaces is zero). A useful sample shape is a rectangular parallelepiped, which has two advantages: one, crystalline samples may be oriented and polished into accurate rectangular parallelepipeds; and two, the sample may be supported at opposite corners, which are mechanically weak, with the result that the transducer contact has minimal effect on the resonance. An example of a RUS apparatus is shown in Fig. 1; this apparatus was designed for small samples, with sample edge lengths of only a few hundred microns. The transducers consist of 0.5 mm wide ribbons of piezoelectric film, only $9\mu\text{m}$ thick.

As mentioned in the introduction, measured resonance frequencies and quality factors, along with information about the resonator, are entered into a computer program which then determines the material properties. Such a computer program typically has two components. One component assumes likely values for the material properties and then calculates the resonance frequencies; this is referred to as the forward program. In the other component, the program adjusts the values of the material properties in the forward program so that the calculated frequencies and quality factors least-squares fit the measured frequencies and quality factors; this is referred to as the inverse program. In the section below, acoustic theory for solids and piezoelectrics is presented in a manner to address the forward problem.

The forward problem is essentially a boundary value problem, and a convenient method for solving such a problem is to minimize a Lagrangian. The minimization procedure should recover the constitutive equations for the solid as well as the boundary conditions, and the solutions would provide the resonance frequencies (eigenvalues) as well as the normal modes of vibration

Fig. 1 An apparatus for measuring elastic constants and acoustic attenuation with resonant ultrasound spectroscopy. The transducers are fashioned from 0.5 mm wide ribbons of $9\mu\text{m}$ thick piezoelectric film. The rectangular parallelepiped sample is supported with two opposing corners lightly touching the transducers.

(eigenfunctions). The constitutive equations are Eqs. (1) through (3), along with $\vec{\nabla} \cdot \vec{D} = 0$ for piezoelectrics. As for fluids, it is assumed that there are small displacements from equilibrium and that η , ζ and κ are zero, so that $D/Dt \simeq \partial/\partial t$ and entropy is constant. The possible boundary conditions for a piezoelectric must be stated: for a point $\vec{r}_{\mathcal{A}}$ on a bare surface of a piezoelectric, $\hat{n} \cdot \vec{D}(\vec{r}_{\mathcal{A}}, t) = 0$; if a portion of the surface ($\mathcal{A}'$) of the piezoelectric has an electrically conducting film, then the boundary condition is $\Phi(\vec{r}_{\mathcal{A}'}, t) = 0$.

In the basic theory, it was stated that for piezoelectrics, there were six constitutive equations and six fields: ρ , $\vec{\Psi}$, S and Φ , but this required that σ_{ij} and $\vec{D}$ be known functions of $e_{ij} = (1/2)(\partial\Psi_i/\partial x_j + \partial\Psi_j/\partial x_i)$ and $\vec{E}$ (or $-\vec{\nabla}\Phi$). Since, as a result of small displacements from equilibrium, the constitutive equations have been made linear, then it may be assumed that the required functions are linear. The linear equations, with constant coefficients, are

$$\sigma_{ij} = c_{ijkl}e_{kl} - d_{kij}E_k = c_{ijkl}\frac{\partial\Psi_k}{\partial x_l} + d_{kij}\frac{\partial\Phi}{\partial x_k} \quad (8)$$

$$D_k = d_{kij}e_{ij} + \epsilon_{kij}E_i = d_{kij}\frac{\partial\Psi_i}{\partial x_j} - \epsilon_{kij}\frac{\partial\Phi}{\partial x_i} \quad (9)$$

where the c_{ijkl} are the elastic constants, the d_{kij} are the piezoelectric constants and the ϵ_{ij} are the dielectric constants. The duplication of the d_{kij} in the two equations is the consequence of a thermodynamic Maxwell relation.

To proceed, it is assumed that all acoustic fields have a time dependence $e^{i\omega t}$, where $\omega = 2\pi f$: $\Psi(\vec{r}, t) = \psi(\vec{r})e^{i\omega t}$ and $\Phi(\vec{r}, t) = \Phi(\vec{r})e^{i\omega t}$. In this case, two time derivatives can be replaced with ω^2 , and the Lagrangian is found to be (Holland, 1968, Holland and Eer Nisse, 1968)

$$\begin{aligned} \mathcal{L} = & \iiint \frac{1}{2} \left[\rho\omega^2(\psi_i)^2 - \frac{\partial\psi_i}{\partial x_j} c_{ijkl} \frac{\partial\psi_k}{\partial x_l} - 2 \frac{\partial\Phi}{\partial x_l} d_{lij} \frac{\partial\psi_i}{\partial x_j} + \frac{\partial\Phi}{\partial x_i} \epsilon_{ij} \frac{\partial\Phi}{\partial x_j} \right] dV \\ & + \iint_{\mathcal{A}'} \frac{1}{2} \left[2(\Phi n_i) d_{ikl} \frac{\partial\psi_k}{\partial x_l} - (\Phi n_i) \epsilon_{ij} \frac{\partial\Phi}{\partial x_j} - \frac{\partial\Phi}{\partial x_i} \epsilon_{ij} (\Phi n_j) \right] d\mathcal{A}' \end{aligned} \quad (10)$$

where the volume integral is over the entire sample and the $\mathcal{A}'$ integral is over the portion of the sample's surface which has an electrically conducting film.

In order to solve the Lagrangian minimization problem numerically, the fields ψ_i and Φ must be expanded in series of basis functions, such as $\psi_i = \mathcal{C}_{im} \mathcal{F}_m(\vec{r})$, $\psi_j = \mathcal{C}_{jn} \mathcal{F}_n(\vec{r})$, where the $\mathcal{C}_{im}$ are coefficients to be determined by minimizing the Lagrangian. Eventually a matrix eigenvalue problem will emerge, and this would be facilitated if $\mathcal{C}_{im}$ had only one index. Thus a single index will be defined for different pairs, e.g. im becomes i , jn becomes ζ . In this case, the indices i, j, m, n become functions of i, ζ , e.g. $i(i)$, $m(i)$, etc. The field expansions become

$$\psi_i(x_1, x_2, x_3) = \delta_{ii(\zeta)} \mathcal{C}_{\zeta} \mathcal{F}_{m(\zeta)}(x_1, x_2, x_3) \quad (11)$$

$$\Phi(x_1, x_2, x_3) = \mathcal{D}_{\kappa} \mathcal{F}_{n(\kappa)}(x_1, x_2, x_3) \quad (12)$$

where in Eq. (11) there is no sum over i . The Lagrangian becomes

$$\mathcal{L} = \frac{1}{2} [\omega^2 \mathcal{C}_i B_{i\zeta} \mathcal{C}_{\zeta} - \mathcal{C}_i A_{i\zeta} \mathcal{C}_{\zeta} - 2 \mathcal{D}_{\kappa} D_{\kappa i} \mathcal{C}_i + \mathcal{D}_{\kappa} E_{\kappa\zeta} \mathcal{D}_{\zeta}] \quad (13)$$

where

$$A_{i\zeta} = \iiint c_{i(i)kj(\zeta)l} \frac{\partial \mathcal{F}_{m(i)}}{\partial x_k} \frac{\partial \mathcal{F}_{n(\zeta)}}{\partial x_l} dV \quad (14)$$

$$B_{i\zeta} = \delta_{i(i)j(\zeta)} \iiint \rho \mathcal{F}_{m(i)} \mathcal{F}_{n(\zeta)} dV \quad (15)$$

$$E_{\kappa\zeta} = \iiint \epsilon_{ij} \frac{\partial \mathcal{F}_{m(\kappa)}}{\partial x_i} \frac{\partial \mathcal{F}_{n(\zeta)}}{\partial x_j} dV - \iint_{\mathcal{A}'} \left[\mathcal{F}_{m(\kappa)} n_i \epsilon_{ij} \frac{\partial \mathcal{F}_{n(\zeta)}}{\partial x_j} + \frac{\partial \mathcal{F}_{m(\kappa)}}{\partial x_i} \epsilon_{ij} \mathcal{F}_{n(\zeta)} n_j \right] d\mathcal{A}' \quad (16)$$

$$D_{\kappa i} = \iiint d_{li(i)j} \frac{\partial \mathcal{F}_{m(\kappa)}}{\partial x_l} \frac{\partial \mathcal{F}_{n(i)}}{\partial x_j} dV - \iint_{\mathcal{A}'} \mathcal{F}_{m(\kappa)} n_l d_{lik(i)l} \frac{\partial \mathcal{F}_{n(i)}}{\partial x_l} d\mathcal{A}' \quad (17)$$

$A_{i\zeta}$ is referred to as the stiffness matrix, $B_{i\zeta}$ is the mass matrix, $E_{\kappa\zeta}$ is the dielectric matrix and $D_{\kappa i}$ is the piezoelectric-elastic coupling matrix. To minimize the matrix version of $\mathcal{L}$, Eq. (13), first take a derivative of Eq. (13) with respect to $\mathcal{C}_i$ and set the result equal to zero:

$$\frac{\partial \mathcal{L}}{\partial \mathcal{C}_i} = \omega^2 B_{i\zeta} \mathcal{C}_{\zeta} - A_{i\zeta} \mathcal{C}_{\zeta} - \mathcal{D}_{\kappa} D_{\kappa i} = \omega^2 B_{i\zeta} \mathcal{C}_{\zeta} - A_{i\zeta} \mathcal{C}_{\zeta} - (D^T)_{i\zeta} \mathcal{D}_{\zeta} = 0 \quad (18)$$

where D^T is the transpose of the matrix D . Taking the derivative of Eq. (13) with respect to $\mathcal{D}_{\kappa}$ and setting the result equal to zero

$$\frac{\partial \mathcal{L}}{\partial \mathcal{D}_\kappa} = -D_{\kappa i} \mathcal{E}_i + E_{\kappa \xi} \mathcal{D}_\xi = 0 \quad (19)$$

By inverting the $E_{\kappa \xi}$ matrix, Eq. (19) can be used to solve for the $\mathcal{D}_\xi$ coefficients in terms of the $\mathcal{E}_i$ coefficients:

$$\mathcal{D}_\xi = (E^{-1})_{\xi \kappa} D_{\kappa \varsigma} \mathcal{E}_\varsigma \quad (20)$$

Substituting for $\mathcal{D}_\xi$ in Eq. (18) gives:

$$0 = \omega^2 B_{i\varsigma} \mathcal{E}_\varsigma - A_{i\kappa} \mathcal{E}_\kappa - (D^T)_{i\xi} (E^{-1})_{\xi \kappa} D_{\kappa \varsigma} \mathcal{E}_\varsigma \quad (21)$$

This can be re-written to give the piezoelectric generalized eigenvalue problem:

$$\left[A_{i\varsigma} + (D^T)_{i\xi} (E^{-1})_{\xi \kappa} D_{\kappa \varsigma} \right] \mathcal{E}_\varsigma = \omega^2 B_{i\varsigma} \mathcal{E}_\varsigma \quad (22)$$

A computer can solve this equation to yield the resonance frequencies $f_v = \omega_v/2\pi$; for a non-piezoelectric solid, one solves Eq. (22) with $D_{\kappa i} = 0$. This constitutes the forward problem for the resonance frequencies, with the matrices containing the material properties. The inverse program for the frequencies could be a standard data-fitting algorithm, such as the genetic algorithm. The quality factors are treated separately, as follows:

The use of $e^{i\omega t}$ in acoustics has two consequences in regard to energy dissipation. From an experimental point of view, the width of the tuning curve may be accounted for by giving each resonance frequency the complex form $f_v(1 + i/2Q_v)$. From a microscopic point of view, the acoustic energy loss in a solid material may be accounted for by giving the elastic constants an imaginary part: $c_{ijkl}(1 + i\varepsilon_{ijkl})$, where ε_{ijkl} is a (usually small) dimensionless loss factor corresponding to the elastic constant c_{ijkl} . Noting that the resonance frequencies f_v of a sample are given by a function of the elastic constants, then if the elastic constants are given an imaginary part, then the resonances frequencies will also acquire an imaginary part, and this must be the same as the experimental form. If the function giving the resonance frequencies in terms of the elastic constants is made complex and expanded to first order in small quantities, then the result is

$$\frac{1}{2Q_v} = \left(\frac{c_{ijkl}}{f_v} \frac{\partial f_v}{\partial c_{ijkl}} \right) \varepsilon_{ijkl} \quad (23)$$

In Eq. (23) there are sums over i, j, k and l , but not over v . The normalized derivatives in Eq. (23) may be determined numerically using the RUS forward program: the elastic constants c_{ijkl} are each in turn given a small change, and the small changes in f_v are calculated; the normalized derivatives are given by the ratios indicated in Eq. (23). A computer program can use Eq. (23) to find the values of the ε_{ijkl} which best fit the measured quality factors.

In the application of RUS to piezoelectrics, the dielectric constants ε_{ij} are usually not adjusted to fit the resonance frequencies; these parameters are easily and accurately determined by sandwiching the piezoelectric in a capacitor of known dimensions and measuring its electrical impedance.

Application of acoustics to liquids

Determination of the equation of state

When the speed of sound of a liquid is measured over an appropriate range of temperature and pressure and combined with measurements of the mass density and isobaric specific heat along one isobar, then relatively stable numerical integration can determine all other thermodynamic properties. Of particular value is the equation of state (EoS) which relates the mass density ρ , the pressure P and the temperature T . In this process, the thermodynamic Maxwell relation

$$\gamma = \frac{c_p}{c_v} = 1 + \frac{T\beta_p^2 c_s^2}{c_p} \quad (24)$$

is used. Even without complete T and P coverage, the speed of sound, as a derivative of density with respect to pressure, provides a sensitive test of a theoretical EoS.

The EoS is of particular importance for reference liquids; an example is water, which can be highly purified and its properties are standardized by the International Association for the Properties of Water and Steam (IAPWS). The current water EoS gets the speed of sound to 0.005%, with relative uncertainties of ± 10 ppm (Wagner and Pruss, 2002; Benedetto et al., 2005; Scalabrin et al., 2007; Bollengier et al., 2019).

The EoS of liquids are needed for general chemical engineering data and for the design of efficient industrial processes, and speed of sound measurements have contributed to the EoS for many important liquids. Liquid n-hexane (Scholz and Richter, 2021) is a working fluid in geothermal, biodiesel and food processing plants, and n-heptane is an extractant and solvent in chemical and food industries. Methanol (Scholz and Span, 2021b) is important as an energy storage liquid for renewable energy sources; during periods of high supply, methanol can be manufactured, and during times of insufficient supply, the methanol may be burned to cover demand. Liquid (mono)-ethanolamine and diethanolamine (Scholz and Span, 2021c) are used to mitigate climate change by

capturing and storing carbon dioxide. Other liquids having numerous important applications and having an EoS developed with acoustics include isobutane (El Hawary and Meier, 2018), ethane (El Hawary and Meier, 2016a), n-butane (El Hawary and Meier, 2016b), propane (Meier and Kabelac, 2012), methane (Cavuto et al., 2020), toluene (Dhakal et al., 2021), cyclopentane (Gedanitz et al., 2015), propylene glycol (Eisenbach et al., 2021), octamethyltrisiloxane and decamethyltetrasiloxane (Thol et al., 2017).

The EoS for liquids under extreme conditions are needed for research in geophysics (Ghiorso and Kress, 2004), planetary sciences and astrophysics, for the understanding of shock waves (McCoy et al., 2017), and for heat transfer in nuclear reactors. In the case for nuclear reactors, the liquids require high heat of vaporization, high thermal conductivity, low viscosity and a wide range of liquid densities, and liquid metals typically satisfy these requirements. Speed of sound measurements at high temperatures and pressures have been performed on liquid alkali metals (Ramasama and Karuppanan, 2019), liquid lead (Kozyrev and Gordeev, 2021), liquid tin (Humrickhouse, 2019) and liquid bismuth (Su et al., 2017). Sound velocity measurements at extreme pressures are made typically in a diamond anvil cell.

Liquid mercury is of special interest; it has a metal-to-non-metal transition which involves inter-atomic pseudo-potentials, and the variation of the speed of sound with pressure and temperature can provide important information. Normally, the sound velocity reflects the long-range electron screened interaction, but at large mercury mass densities, the sound velocity probes the repulsive part of the potential (Ayrinhac et al., 2014).

Viscosity

The measurement of shear viscosity (as well as mass density) of a liquid is often accomplished with a “quartz microbalance”, which is a resonator with a flat surface oscillating back and forth in the plane of the surface. If a bulk liquid, film of liquid or drop of liquid is in contact with the surface, then the frequency of the resonator is decreased by an amount which can be used to determine the mass density of the liquid, and the quality factor of the resonance is decreased by an amount which can be used to determine the shear viscosity of the liquid (Crane and Fischer, 1979). Typically the resonator is a quartz crystal cut so as to have a thickness shear mode which has the least temperature dependence (in order to facilitate measuring the temperature dependence of the shear viscosity). Longitudinal mode resonators for measuring liquid bulk viscosity may also be used (Taskoprulu et al., 1961), and piezoelectrics other than quartz may be used (Bannai and Wakatsuki, 2003).

With the advent of microelectromechanical systems, atomic force microscopes and other devices made with microelectronic fabrication techniques, other resonator-based viscometers have been devised. Typically a quartz tuning fork is used, either completely immersed in the liquid (Voglhuber-Brunnmaier et al., 2019; Zhang et al., 2020), or with a needle appendage extended through a liquid surface (Fernandez et al., 2018). A variation employs a cantilever vibrator with a needle which immerses a small sphere in the liquid (Patois et al., 2000). These viscometers require complicated analyses, and it is not clear if there are advantages over the microbalance resonator.

As discussed earlier, a particularly useful device in acoustics is the double Helmholtz resonator, which consists of two volumes connected by a neck. If the neck is an appropriately sized capillary, then such a resonator is a “Greenspan viscometer” (Gillis et al., 2003); the resonance frequency and quality factor can be used to determine the mass density or adiabatic bulk modulus, and the shear viscosity of the fluid. The Greenspan viscometer is a standard for determining viscosity for gases. Inexplicably, only single Helmholtz resonators have been used for liquids (Ehlers, 1960; Chen and Park, 2019).

Colloids

Sound waves experience novel effects when propagating in colloids, which are liquids containing insoluble particles of a particular size (typically 1–1000 nm) and density. If the wavelength of longitudinal sound is about the same as the size of the particle, then the sound will experience maximum scattering, and with sufficient interaction, an acoustic shear wave can propagate (Forrester et al., 2016). If the density of particles is sufficiently large so that the particles can touch and undergo a percolation transition, then the sound wave will exhibit a significant change in speed and indicate power law behavior as a function of particle density (Ye et al., 1993). Measurements of the attenuation of sound can provide information about the interactions between the particles (Lebedev-Stepanov and Rybak, 2011), and acoustic measurements as a function of temperature can indicate that at low temperatures particles may agglomerate and form larger particles (Blaudez et al., 1994). Since longitudinal sound waves modulate the density of the particles, and since the scattering of light by a colloid depends on the density of particles, then the combined effect (the photo-acoustic effect) can be used to further probe and image effects in a colloid (Fuentes-Oliver et al., 2021).

Liquid crystals

Acoustic measurements have a number of ways of obtaining information about liquid crystals, which are liquids composed of elongated, rod-like molecules. In such liquids, the molecules may be unaligned and disordered in position, aligned and disordered in position, or aligned with various patterns in position, and there can be phase transitions between the different possibilities. The modes of acoustic propagation and attenuation are numerous, and it will not be possible to provide a comprehensive treatment here; however, there are review texts (de Gennes, 1993; Yang and Wu, 2015; Larionov et al., 2017). Some representative acoustics research includes anisotropic wave propagation (Biscari et al., 2014), the effect of lattice defects in a cubic crystal-like phase (Fujii and Henrich, 2021), viscoelastic effects (Turzi, 2016) and relaxation effects near a phase transition (Balcerzak, 2005).

Containerless confinement of liquids

One of the problems with measurements on liquids, particularly in undercooled metastable states, is that the walls of a container may have a significant effect on the phenomenon under study. This can be overcome with “containerless” measurements made possible with acoustic levitation and confinement; these are nonlinear acoustic effects which may be explained as follows:

In an acoustic standing wave, fluid particles at a node are motionless while fluid particles at an antinode are oscillating back and forth with a maximum amplitude. If one time averages, then the averaged velocity of the fluid is zero everywhere. However, if one time averages the square of the velocity, U^2 , then one gets zero at a node and a maximum value at an antinode. Bernoulli’s law states that where U^2 is large, then pressure is diminished; the result is that there is a pressure gradient from nodes to antinodes. A gas (possibly inert) resonator may be fabricated so that a vertical standing wave can levitate a liquid mass, and horizontal standing waves, with pressure minima, can hold the liquid in a selected position. If the horizontal standing waves are driven 90 degrees out of phase, then the liquid mass may be made to rotate. In a microgravity application, the levitating wave may become a vertical positioning wave. When providing a containerless environment for liquids, acoustics is not the probe; the probe may be light, synchrotron radiation or a neutron beam (Kohara et al., 2018).

Application of acoustics to solids

The use of acoustics to determine elastic constants and piezoelectric constants is a vast enterprise, and review books and articles have been mentioned in the introduction. Only a few representative examples will be mentioned here.

Diamond

RUS was used to measure, at unprecedented precision, all of the elastic constants for a single crystal of diamond over the temperature range from 10 K to 322 K (Migliori et al., 2008). The published paper shows in detail how the results can be used to determine the phonon distribution function, the Debye temperature parameter (used in the Debye-Einstein model for the specific heat and the Bardeen-Cooper-Schreifer theory for superconductivity), parameters related to interatomic potentials, and the Grüneisen parameter which reflects anharmonic and finite temperature effects.

Plutonium

Plutonium is one of the most complicated and puzzling materials in condensed matter physics. It has six different crystal structures, extreme elastic anisotropy, negative thermal expansion, large volume changes during structural transitions, a relatively incomprehensible electronic structure and aging effects (defect formation) resulting from its own nuclear radiation. During the time when a satisfactory explanation of the physics was not available, it was feared that aging could make old nuclear weapons unreliable, so that fresh nuclear weapons had to be manufactured. Fortunately, RUS measurements on old and new plutonium under a comprehensive array of conditions significantly changed the situation (Mairov et al., 2017; Keppens et al., 2010). The vastly enhanced understanding of aging has improved the confidence in nuclear weapons, and this has supported a considerable reduction of the stockpile of nuclear weapons. The plutonium research has been a notable benefit of acoustics to society as well as to condensed matter physics.

Thermoelectric devices employing clathrates

Thermoelectric materials could make very useful devices: by passing an electrical current through them, they could provide cooling with no moving parts; by delivering heat to them (possibly waste heat from an engine or industrial process) they could generate electricity. However, there is a difficulty, because for large heat transport, large electrical currents would be involved, so that a thermoelectric material should have high electrical conductivity. However, a general property of solids is that a large electrical conductivity is almost always accompanied by a large thermal conductivity, and this conductivity would “short out” any desired temperature gradient across the thermoelectric device. What is needed is some unusual material which has a large electrical conductivity (meaning low scattering of electrons) and a small thermal conductivity (meaning high scattering of thermal lattice vibrations, or phonons). Materials which have possibilities are the clathrates; these materials are semiconductors (which can have satisfactory electrical conductivity) with voids in their lattice structure which can hold foreign “guest” atoms. Through spring-like interactions with the host atoms at the surface of the void, the guest atoms can have several modes of vibration and can provide a relatively large scattering cross-section for thermal phonons, thereby reducing the thermal conductivity. These guest vibrators also have a dramatic effect on the temperature dependence of the clathrate’s elastic constants, as illustrated in Fig. 2. The solid line in the figure shows the behavior of an elastic constant for nearly all materials (excluding phase transitions); the dashed line is taken from a RUS measurement on a clathrate, showing a radical deviation. (Zeroc et al., 2004).

Fig. 2 Illustration of the temperature behavior of most elastic constants (solid line), and the dramatically different behavior of clathrates (dashed line). The acoustics of these materials make them potential candidates for high performance thermoelectrics.

Piezoelectrics

Measurements of elastic and piezoelectric constants have been undertaken for decades. However, early measurements required that samples be re-cut, re-polished, have transducers re-attached, and have conducting films re-deposited, sometimes as many as five times. There was so much bother that measurements were often made at room temperature only, and because measurements were made under so many different conditions, the results were often inconsistent. With RUS, one sample can be mounted once, held at a controlled temperature, and have a spectrum of frequencies measured in a matter of minutes; the measurement can then be repeated with only the temperature (or other external field) changed. For each temperature, the spectrum of frequencies may be used to determine a complete and self-consistent set of elastic and piezoelectric constants.

Such measurements have been made for classic piezoelectrics, including quartz (Ogi et al., 2006), lithium niobate and lithium tantalate (Tarumi et al., 2012), potassium titanyl phosphate (Zhang et al., 2016), tourmaline (Pandey and Schreuer, 2012) and lead-zirconate-titanate (Li et al., 2019; Zhang et al., 2017). Measurements have been made on exotic materials showing giant piezoelectric effects (relaxor-based ferroelectric single crystals) including lead-magnesium-niobium-lead-titanate and lead-indium-niobium-lead-titanate (Schreuer, 2002; Delaunay et al., 2008; Chen et al., 2019). For promising practical applications, measurements have been made on high-temperature piezoelectrics, including langstate (Davulis and da Cunha, 2013) and langasite (Ogi et al., 2003). RUS has also been used to study symmetry breaking in crystals which normally would not be piezoelectric (Aktas et al., 2021).

The search for a supersolid

In 2004, an experiment indicating the probable observation of a supersolid phase of helium four was reported (Kim and Chan, 2004). The experiment involved measuring the temperature dependence of the resonance frequency of a torsional oscillator, which consisted of a torsion rod connected to a cylindrical “bob”; solid helium was confined inside the bob. An elementary model of the oscillator was that of a torsional spring connected to a rigid-body bob, so that the resonance frequency was simply related to the torsional spring constant divided by the moment of inertia of the bob. Such a model was used with great success in the study of superfluid helium; the principle was that when the helium became superfluid (or supersolid), then the helium would decouple from the rest of the bob and no longer fully contribute to the moment of inertia, and the resonance frequency would increase. While this elementary model is satisfactory for liquid helium, it is insufficient for solid helium. The problem is that there is no such thing as a rigid body, and as indicated in the theory section for acoustics in solids, the proper model for the resonance frequency of the torsional oscillator requires knowing the mass density and shear modulus throughout the entire apparatus. There are two reasons why the elementary model was satisfactory for liquid helium but not for the solid: one, the shear modulus of a liquid is always zero and has no temperature dependence; and two, it was already known that the shear viscosity of liquid helium changed abruptly at the superfluid transition temperature. By contrast, solid helium has a shear modulus which could change with temperature regardless of a supersolid transition, but at the time its temperature dependence was unknown. In 2007 the temperature dependence of the shear modulus was measured with an independent acoustic method (Day and Beamish, 2007), and it was found that it did change in an anomalous fashion in the temperature range of the supersolid observations and could account for the change in the torsional oscillator resonance frequency. While the temperature dependence of the solid helium shear modulus was not related to a supersolid, it was interesting in its own right, involving the thermally activated depinning of helium three impurities from lattice defects in a quantum solid (Day and Beamish, 2007).

Another application of acoustics

In condensed matter theory, one might determine material properties by using the energies (quantum or classical) of individual atoms and calculating averages over a large collection. Experimentally, one cannot measure the energies of individual atoms, but one can measure the temperature and then determine averages with a distribution function. In order to make the connection between energies in the theory and temperatures in the experiment, one needs the Boltzmann constant, which has been one of the least accurately known of the fundamental physical constants. This has changed because of acoustic measurements in spherical resonators, where a speed of sound was measured to high accuracy, and by calibrating the resonator with microwaves, the measured speed was related to the speed of light, a defined physical constant. The fluid in the spherical resonator was low density helium gas, for which the theoretical status had become so advanced that its speed of sound could be calculated to high accuracy. By comparing the experimental and theoretical results, the Boltzmann constant could be determined to such high accuracy that it could be made a defined fundamental constant (Pitre et al., 2017). Furthermore, the acoustic method is now the standard for measuring temperature. While the measurements do not involve a liquid or solid, they are certainly a notable contribution from acoustics to condensed matter physics.

Conclusion

Acoustic measurements are being made easier, over a wider scope of materials, and under a broader range of conditions. The results are increasingly more precise, accurate and self-consistent. Information obtained from acoustic measurements about condensed matter physics has led to improved a priori calculations and predictions of behavior in conditions not readily available for study. It is anticipated that this process will continue and grow in the future.

Abstract

Anderson localization provides a challenge to numerical approaches due to the inherent randomness, and hence absence of simple symmetries, in its discrete Hamiltonian representation. Numerous algorithmic approaches have been developed or adopted from other fields and have been collected in this encyclopedia entry. In the discussions below, the emphasis is on the numerical algorithms for localization, while the discussion of the physics of localization is referred to in companion entries by Elgart and Oganesyan in this encyclopedia.

Key points

- The article reviews existing numerical algorithms used when studying Anderson localization and gives relevant references
- algorithms for data generation
 1. diagonalization strategies such as exact methods, sparse-matrix methods, kernel-polynomial methods
 2. iterative/quasi-1D algorithms such as the transfer-matrix and the Green function method
 3. renormalization-inspired numerical approaches
- data analysis algorithms
 1. energy-level and -ratio statistics
 2. wave function statistics and multi-fractal analysis
 3. finite-size scaling algorithms, with and without assuming a scaling form
- current challenges
 1. numerical algorithms in use for data generation and analysis of interacting disordered systems
 2. algorithms based on machine learning strategies

Introduction

Anderson localization, as reviewed in this encyclopedia in other entries, cannot be solved analytically in dimensions two and above (Stollmann, 2001). Hence much effort has been focused on developing efficient numerical tools. In its usual form, the discrete Anderson Hamiltonian (Anderson, 1958) is given by the matrix elements

$$H_{ab} = \varepsilon_a \delta_{ab} - t_{ab} \delta_{\langle a, b \rangle}, \quad (1)$$

where ε_a is the potential onsite disorder and δ_{ab} the Kronecker delta, while t_{ab} denotes the kinetic hopping energy with $\delta_{\langle a, b \rangle}$ non-zero when lattice sites $\mathbf{a} = (a_1, a_2, \dots, a_d)$, $\mathbf{b} = (b_1, \dots, b_d)$ are within a defined distance relationship on a discrete, d -dimensional lattice $\mathcal{L}_d$ — usually the nearest-neighbor separation on $\mathcal{L}_d$. With $|\mathcal{L}_d|$ counting the number of lattice sites, H_{ab} is an $|\mathcal{L}_d| \times |\mathcal{L}_d|$ matrix. The time-independent single-particle Schrödinger equation can then be written as

$$\varepsilon_a \Psi_a - \sum_{\mathbf{b} \in \mathcal{L}_d} t_{ab} \delta_{\langle a, b \rangle} \Psi_b = E \Psi_a \quad (2)$$

with $\Psi_a = \Psi_{a_1, \dots, a_d}$ the coefficients of the wave function $\Psi = \sum_{\mathbf{a} \in \mathcal{L}_d} \Psi_a |\mathbf{a}\rangle$ in a suitable basis $|\mathbf{a}\rangle$ and E the energy.

Fig. 1 (A) Extended, (B) critical and (C) localized wave function probabilities for the three-dimensional Anderson model with periodic boundary conditions at $E \approx 0$ with $N = 200^3$ and $W = 15, 16.5$ and 18 , respectively. Every site $\mathbf{a}$ with probability $|\psi_{\mathbf{a}}|^2$ larger than the average $1/|\mathcal{L}_3|$ is shown as a box with volume $|\psi_{\mathbf{a}}|^2 |\mathcal{L}_3|$. Boxes with $|\psi_{\mathbf{a}}|^2 |\mathcal{L}_3| > \sqrt{1000}$ are plotted with black edges. The color scale along the bottom right edge distinguishes between different slices of the system. The eigenstates have been computed with JADAMILU (Bollhöfer and Notay, 2007) as described by Schenk et al. (2008).

In its simplest form, the Hamiltonian (1) is studied on a d -cubic lattice with $t_{ab} = t_{ba} = t = 1$ for all nearest-neighbors $\mathbf{a}, \mathbf{b}$ and $\varepsilon_{\mathbf{a}}$ independent and identically distributed random numbers $\in [-W/2, W/2]$. Hence the parameter W/t expresses the strength of the disorder. See Fig. 1 for examples of Ψ in $d = 3$. Since numerical studies of Anderson localization began to emerge in the late 1970s, this set-up has of course been much varied to include more complicated situations (Kramer and MacKinnon, 1993). Examples include variations in d from 1 to ∞ , changes in the lattice structure, symmetry and topology, changes to and additional disorder or correlations in the $\varepsilon_{\mathbf{a}}$ and t_{ab} , as well as inclusion of spin-, external field and interaction effects (Brandes and Kettemann, 2003). The common theme unifying all the studies is the absence of symmetries in H due to the disorder which in turn prevents a simple restructuring of the matrix into much smaller irreducible blocks (Evers and Mirlin, 2008). Connecting the properties of such a single large-block matrix with the physics of Anderson localization is the challenge taken on by the numerical algorithms listed in this encyclopedia entry.

Exact diagonalization

Given an invertible matrix (1), the most straightforward approach is to use standard *full* matrix methods to compute eigenvalues and eigenvectors such as given by the LAPACK library routines (Anderson et al., 1999) and their many highly optimized implementations. At the time of writing this entry, matrices of sizes up to $\sim 10^4 \times 10^4$ can be readily studied with this method. However, as an average over many different disorder realizations is always necessary to find physically reliable results, already such matrix sizes can lead to many weeks of computing. Many of the algorithms mentioned below were conceived to allow for faster availability of results, while at the same time leading to a more limited set of computed information.

When $\delta_{(\mathbf{a}, \mathbf{b})}$ is sufficiently short-ranged, many of the matrix elements H_{ab} are equal to 0. In this case, it can be advantageous to use *sparse* matrix methods. Such methods construct selected regions of the eigenspectra using repeats of an optimized matrix-vector product computation for $H_{ab}\Psi_{\mathbf{b}}$ following the classic power series algorithm (Horn and Johnson, 1985). For the Anderson problem, the implementation of the Lanczos variant by Cullum and Willoughby (2002) is particularly useful since the disorder removes spectral degeneracies such that the “ghost eigenvalues” coming from the implementation can be readily identified. Polynomial convergence acceleration can often further improve convergence (Elsner et al. 1999). Coupling the sparse-matrix approach with advantages in iteratively solving coupled systems of equations, Schenk et al. (2008) found that a Jacobi-Davidson approach coupled with shift-and-invert techniques Parlett (1980) can construct eigenstates of size up to $350^3 \times 350^3$ in the numerically most demanding region around the center of the spectrum within a reasonable time. Weiße et al. (2006) showed that similar sizes can be reached using kernel-polynomial methods when coupled with efficient recursive polynomial expansion techniques. The method is particularly efficient in determining a change in the *distribution* of the local density of states as a criterion for Anderson localization.

Quasi 1D methods

Repeated matrix-vector computations also underlie the celebrated transfer-matrix method (TMM) (Pichard and Sarma, 1981; MacKinnon and Kramer, 1983). The main idea is that it is often possible for a suitable $\mathcal{L}_d$ to rewrite (2) as

$$\begin{pmatrix} \psi_{n+1} \\ \psi_n \end{pmatrix} = \begin{pmatrix} \tau_{(n+1, n)}^{-1}(E\mathbf{1} - \mathbf{H}_{d-1}) & -\tau_{(n+1, n)}^{-1}\tau_{(n, n-1)} \\ \mathbf{1} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \psi_n \\ \psi_{n-1} \end{pmatrix}. \quad (3)$$

Fig. 2 Schematic diagram of the TMM method for the example of a $d = 2$ Anderson model. At slice n and position m , one needs to know the (past) $\psi_{n-1,m}$ value, the (present) values of $\psi_{n,m}$ and $\psi_{n,m \pm 1}$ and then compute the (future) value of $\psi_{n+1,m}$. The red lines indicate the orthonormalizations for ψ needed for numerical stability. The diagram at the top shows the behavior of the typical convergence for a Lyapunov exponent measured after each reorthonormalization, the actual number of reorthonormalization used here exceeds 10^4 . The colors of $\psi_{n,m}$ are chosen such that they indicate the eventual convergence for $n \rightarrow \infty$.

Here, $\psi_n = (\psi_{n,1}, \dots, \psi_{n,|\mathcal{L}_{d-1}|})$ are transfer states along a single spatial coordinate in $\mathcal{L}_d$ while $\mathbf{H}_{d-1}$ is the $|\mathcal{L}_{d-1}| \times |\mathcal{L}_{d-1}|$ Hamiltonian along the remaining $d-1$ directions and $\tau_{\langle n+1,n \rangle}$ denotes the connectivity matrices along the transfer direction (cp. Fig. 2). The advantage of singling out a special direction along which to study wave function progression lies in the fact that 1D localization is mathematically known to be very strong which usually translates into fast algorithmic convergence.

With T_n the $2|\mathcal{L}_{d-1}| \times 2|\mathcal{L}_{d-1}|$ (local transfer) matrix in (3), we define the global transfer matrix $\mathcal{T}_{\mathcal{L}_{d-1}}(|\mathcal{L}_1|) = \prod_{n=1}^{|\mathcal{L}_1|} T_n$. Then $\lim_{|\mathcal{L}_1| \rightarrow \infty} (\mathcal{T}\mathcal{T}^\dagger) = \exp[2 \text{diag}(\gamma_1, \dots, \gamma_{2|\mathcal{L}_{d-1}|})|\mathcal{L}_1|]$ with Lyapunov decay exponents $\gamma_1, \dots, \gamma_{2|\mathcal{L}_{d-1}|}$, ordered $\gamma_1 > \gamma_2 > \dots > \gamma_{|\mathcal{L}_{d-1}|} > 0 > -\gamma_{|\mathcal{L}_{d-1}|} > \dots > -\gamma_1$, i.e. the Lyapunov exponents come in pairs $\pm\gamma_m$, $m = 1, \dots, |\mathcal{L}_{d-1}|$ due to the symplectic structure of the T_n . The positive $\gamma_{\mathcal{L}_{d-1}}$ indicates the largest extend of the states along the transfer direction, leading to the definition of the (largest) localization length as $\lambda_{\mathcal{L}_{d-1}} = 1/\gamma_{\mathcal{L}_{d-1}}$. Implicit in the convergent construction of the $\lambda_m = 1/\gamma_m$ is the self-averaging over the disorder along the transfer direction. An error analysis in the statistical changes of the λ_m has to be made when computing the stopping criterion of the TMM (MacKinnon and Kramer, 1983). The $|\mathcal{L}_d - 1|$ dependence of $\lambda/|\mathcal{L}_d - 1|$ lends itself to finite-size scaling and can hence be used to characterize universal properties of Anderson localization. A direct connection to the typical conductance is also known (Pichard and Sarma (1981)).

Generalizations of the TMM include different lattice structures (Schreiber and Ottomeier, 1992; Eilmes et al., 2008) as well as non-standard transfer directions (Frahm et al., 1995). For disorder distributions for whom self-averaging is not applicable, a forward/backward variant of the TMM has been given as well (Frahm et al., 1995; Ndawana et al., 2004). A recent reevaluation of the idea of self-averaging has also led to the first efficient implementation of TMM on massively-parallel computing architectures (Slevin and Ohtsuki, 2018).

Computing matrix elements of the resolvent $(E1 - \mathbf{H}_{d-1})^{-1}$ leads to a conceptually very similar recursion setup compared to (3). This so-called Green function method (MacKinnon and Kramer, 1981) again provides access to localization lengths and conductivity for chosen values of $\mathcal{L}_{d-1}$. An implementation of the method along a non-standard transfer direction has been given by Von Oppen et al. (1996).

Renormalization and decimation methods

Real-space renormalization approaches provide another starting point for studying Anderson localized systems. Here the idea is that an individual lattice site can be "removed" from $\mathcal{L}$, leading to a modified H_{ab} . For example, the decimation method (Aoki, 1982;

Fig. 3 Schematic of real-space decimation procedures using (A) Green function renormalization in $d = 2$ and (B) local energy renormalization for hopping (left of $\downarrow$) and onsite terms (right of $\downarrow$) in, e.g., $d = 1$. In both schematics, solid lines and circles indicate unrenormalized hopping (t_{12}, t_{23}, t_{34}) and onsite energies ($\epsilon_1, \epsilon_2, \epsilon_3$), respectively, while the dashed and dotted lines and circles represent renormalized values (t' and ϵ'_1, ϵ'_3). The (A) horizontal and (B) vertical arrows represent to renormalization progression in both schemes.

Leadbeater et al., 1999), finds $H_{ab}' = H_{a,b} + (H_{a,|\mathcal{L}_d|}H_{|\mathcal{L}_d|,b})/(E - H_{|\mathcal{L}_d|,|\mathcal{L}_d|})$ after removal of the site $(|\mathcal{L}_d|, |\mathcal{L}_d|)$ while the Green function remains unchanged. In this way, the decimation of lattice sites can proceed until a sufficiently small Hamiltonian has been constructed to use the exact diagonalization routines reviewed above (cp. Fig. 3A). Another recent variant of real-space normalization makes use of the information encoded in the ε_a and $t_{a,b}$ values. By recursively elimination those sites with the largest local energy scale $\Omega = \max_{a,b} \{|\varepsilon_a|, |t_{a,b}|\}$, (Mard et al., 2014, 2017) continue until only a single renormalized link $\varepsilon_\alpha' - t_{\alpha,\beta}' - \varepsilon_\beta'$ is left. This last link can then be used to compute transport properties, including their disorder W dependence and the scaling behavior (cp. Fig. 3B). The method is applicable for $1 \leq d < \infty$. In $d = 2$, the approach is similar in spirit to the real-space renormalization approach used for localization in a magnetic field (Cain and Römer, 2005).

Energy-level statistics

The distribution of energy-level spacings $\delta_n = E_{n+1} - E_n$ in the eigen-spectra $\{E_n\}$ of Anderson-type systems has long been known to provide a marker able to distinguish between extended and localized eigenstates Ψ (Altshuler and Shklovskii, 1986; Evangelou and Economou, 1992; Shklovskii et al., 1993) with distribution functions $P(\delta)$ of the spacing following the three Dyson ensembles — e.g. with the Gaussian orthogonal ensemble (GOE) corresponding to real-symmetric matrices invariant under orthogonal transformations — (Dyson, 1962; Shklovskii et al., 1993) and generalizations thereof (Altland and Zirnbauer, 1997). Often, the integrated distribution function $I(\delta) = \int_0^\delta P(\delta')d\delta'$ is a numerically more stable indicator (Zhong et al., 1998). More detailed tests of the spectral properties such as the Δ_3 and Σ_2 statistics have also been employed (Mehta, 2004; Hofstetter and Schreiber, 1993). As usual, the $|\mathcal{L}_d|$ dependence of these quantities can be used for scaling; convenient estimates of $P(\delta)$, etc., have been given based on Wigner surmises (Shklovskii et al., 1993).

However, before a detailed comparison with predictions of random matrix theory is possible, the region of the spectrum under investigation has to be *unfolded* so that the unfolded density-of-states is constant Hofstetter and Schreiber (1993). This adds a possible source of numerical uncertainty for systems with large fluctuations in the density-of-states. Recently, it has been suggested to study ratios of level spacings such as $0 \leq r_n = \min \{\delta_n, \delta_{n-1}\} / \max \{\delta_n, \delta_{n-1}\} \leq 1$ (Oganesyan and Huse, 2007) and others (Luo et al., 2021) and their distributions instead (cp. Fig. 4A). For such ratios, the unfolding procedure is no longer necessary, while mean and moments are still accessible via surmises and even exact results exist (Atas et al., 2013; Giraud et al., 2022). A recent application of r -value statistics to characterize the Anderson transition can be found in (Šuntajs et al., 2021).

Wavefunction statistics and multi-fractal analysis

Unsurprisingly, the characteristics of the eigenstates of (1) are also useful when studying the localization properties. In the simplest situation, the participation number $\mathcal{P} = \left(\sum_{a \in \mathcal{L}_d} |\Psi_a|^4 \right)^{-1}$ (Wegner, 1980) measures how many sites in $\mathcal{L}_d$ participate in the spatial extend of a given Ψ . E.g. for a localized Ψ , $\mathcal{P} \sim 1$, whereas for an extended Ψ , $\mathcal{P} \sim |\mathcal{L}_d|$. The universal statistical properties of Ψ can

Fig. 4 (A) Distributions of the energy level ratios r (dark and light blue) and $|z|$ (dark and light red) for a $d = 3$ Lieb model with 44^3 sites (Liu et al., 2020) and averaged over $\sim 8 \times 10^6$ ratios for each curve. Darker colors denote slightly larger disorders. The black dashed and solid lines indicate the exact $P_{\text{Poisson}}(r)$ and a surmise for $P_{\text{GOE}}(r)$. No such predictions are yet known for $P(|z|)$ (Luo et al., 2021). (B) Ensemble-averaged singularity spectrum $f_q(\alpha_q)$, parameterized by q -moments, for Kohn-Sham wave functions computed via density-functional theory of Si:P with 22^3 atoms of which 140 are P impurities (Carnio et al., 2019a). The spectrum has been sampled for values of $q = 5, 4.75, \dots, -1.75, -2$ (decreasing from left to right) in the bulk of the impurity band at 0.2495 eV below the Fermi energy. Blue diamonds show the results for the ensemble of the first 100 disorder realizations, while red circles indicate the results from all 597 available realizations. Simple error bars, without data point, indicate the symmetrized spectrum of the full ensemble. Dashed lines indicate $f_0 \equiv 3$ and $f_1(\alpha) = \alpha$. The dotted line represents the spectrum for the standard cubic 3D Anderson model at criticality, reproduced from Rodriguez et al. (2011), while the dot-dashed line shows the fit to a parabolic approximation (Evers and Mirlin, 2008). The two horizontal lines are guides to $f = 0$ and 3.

be computed as well, with the Porter-Thomas distributions capturing the behavior at weak disorder while the systematic corrections at larger disorder have been calculated in a series of works (Mirlin, 1999). Directly at the Anderson metal-insulator transition, e.g. in three-dimensions, Ψ has the scaling properties of a multifractal (Janssen, 1998). The full multifractal spectrum can be shown to be system-size independent and the moments of the multifractal distributions can be used to characterize the critical properties of the transition (Rodriguez et al., 2011), via finite-size scaling. A typical multi-fractal $f(\alpha)$ spectrum is shown in Fig. 4B.

Finite-size scaling

The finite-size scaling approach to second order phase transitions has been well documented by now (Abrahams et al., 1979; Belitz and Kirkpatrick, 1994; Slevin and Ohtsuki, 1999). Roughly speaking, finite-size scaling implies the collapse of data for different parameters such as E and W onto a single scaling curve when their system size $|\mathcal{L}_d|$ dependence is adjusted as well (Slevin and Ohtsuki, 1999).

For the Anderson localization problem, there exist two different numerical approaches. In the absence of a phase transition, i.e. in $d \leq 2$, or when the functional form of the transition is not known, one can attempt to simply construct the data collapse of a suitably chosen quantity, such as the localization length $\lambda_{|\mathcal{L}_d|}$ or a multifractal moment τ_q , by minimization of the overlap between curves. In this approach, the shift needed to achieve this minimal overlap defines a scaling parameter ξ and its parameter dependence on E or W . For the Anderson transition in three dimensions, the behavior should be a good approximation of $\xi \propto |E - E_c|^{-\nu}$ or $\xi \propto |W - W_c|^{-\nu}$. This defines the critical transition points E_c , W_c as well as the critical exponent ν .

The second, more modern approach, starts by assuming a scaling form for $\xi_{|\mathcal{L}_d|}$, say

$$\xi_{|\mathcal{L}_d|}(F) = a_{00} + a_{01}(F/F_c - 1)|\mathcal{L}_d|^{1/\nu} + |\mathcal{L}_d|^{-\gamma} \left[a_{10} + a_{11}(F/F_c - 1)|\mathcal{L}_d|^{1/\nu} \right], \quad (4)$$

and then fits the parameters a_{ij} , ν and γ to allow the best possible fit to the accumulated data points by a non-linear regression (Slevin and Ohtsuki, 1999) for either energy ($F = E$) or disorder ($F = W$) dependence (cp. Fig. 5). This more systematic approach allows the inclusion of the irrelevant scaling exponent $\gamma > 0$ as shown in the example. The accuracy of a fit is quantified via χ^2 analysis. When constructing the scaling function ξ in powers of relevant and irrelevant corrections, one has to take care that the fit with the best χ^2 statistics is also robust with respect to changes in the range of energies and disorders considered as well as stable within the computed accuracy when increasing the complexity of the fit function. It is this second finite-size scaling approach, together with high accuracy data computed by the TMM or sparse matrix diagonalization coupled with multifractal analysis as outlined above, which currently gives the accepted best-fit estimates of the critical properties at the Anderson transition (Slevin and Ohtsuki, 1999).

Localization and many-body interactions

The possibility of including the influence of interactions on the Anderson localization problem has always intrigued the community and was mentioned already by Anderson (1958). Numerically, the problem becomes much harder since the number of states in Hilbert space grows from $\propto |\mathcal{L}_d|^d$ to $\propto \exp |\mathcal{L}_d|$ while the requirement to perform the disorder averaging remains. Early investigations concentrated on studying the influence of disorder on the ground states of interacting systems (Giamarchi, 2003; Schuster et al., 2002). Mostly, progress was based on numerical methods adopted from clean interacting systems with methods such as the density-matrix renormalization group approach (White, 1992; Schollwöck, 2005) and exact diagonalization most commonly used. For the many-body localization problem (see article in this encyclopedia), the complete spectrum is often of more interest, so

Fig. 5 Reduced localization lengths $\Lambda_M = \lambda_{|\mathcal{L}_2|}/M$, with $M = |\mathcal{L}_2|$ the size of the TMM bar, versus (A) W or (B) $\xi(W)/M$ for $E = 0$ of a $d = 3$ Anderson model defined on an fcc lattice (Eilmes et al., 2008). Different symbols and colors denote increasing $M = 3(\bullet), \dots, 15(\times)$. Panel (C) shows the constructed $\xi(W)$ scaling parameter function (black line) with divergence at $W_c = 26.73(1)$ (vertical dotted line) and the computed $\xi(W)$ values for $W_i = 26, \dots, 27.5$ (circles).

exact diagonalization is often the method of choice, severely restricting the spatial size of systems while still retaining a relatively large Hilbert space (Oganesyan and Huse, 2007). Recently, applications of shift-and-invert (Pietracaprina et al. (2018) as well as polynomial convergence acceleration Sierant et al. (2020) (cp. Section “Exact diagonalization”) have further increased the available system size and modern Hilbert-space renormalization schemes known as tensor network methods are becoming more main stream (Montangelo (2018)). Renormalization schemes adaptive to the disorder, such as implementations of the strong-disorder renormalization group (Hikihara et al., 1999; Goldsborough and Römer, 2014) already mentioned above for the non-interacting case, might also provide a way forward.

Approximate methods such as the time-honored Hartee-Fock (Weidinger et al., 2018; Oswald and Römer, 2020) as well as density-functional-theory methods (Harashima and Slevin, 2014; Carnio et al., 2019b) have also begun to be applied to the localization problem. Particularly the latter offer the exciting possibility of providing a material-specific approach to studies of Anderson localization (Carnio et al., 2019a). In this context, one should also mention the typical medium dynamical cluster approximation for disordered electronic systems (Aguiar et al., 2009) which can now also be used to incorporate density-functional-theory-derived potentials, the effect of multiple bands, non-local disorder, and electron-electron interactions (Terletska et al., 2018). Another approximate method that incorporates the full spatial variations of wave functions and *local* interactions effects is the statistical dynamical mean field theory (Dobrosavljević and Kotliar, 1997; Miranda and Dobrosavljević, 2012). Local interactions are included self-consistently through effective correlated single-impurity problems (CSIP) (Georges et al., 1996). In the disordered context, each site defines a different CSIP whose local self-energy is fed back into the lattice self-consistent loop. In the non-interacting limit the formulation is exact. It has been used to study the disordered Mott transition (Miranda and Dobrosavljević, 2012; Suárez-Villagrán et al., 2020) and disordered heavy fermion systems (Miranda and Dobrosavljevic, 2001), where a distribution of Kondo temperatures is a conceptually useful byproduct.

Machine learning

A seemingly new approach has become available to the numerical study of Anderson localization with the emergence of the machine learning paradigm. Instead of specifying in detail which physical aspects of data to concentrate on, say transport properties such as λ , conductivity or multifractal moments τ_q , the data-driven machine learning approach can be used to find Anderson transitions for variants of the model Hamiltonian (1) when training deep learning networks on, e.g., the standard cubic Anderson model (Ohtsuki and Ohtsuki, 2016). With this form of *supervised* machine learning of Anderson localization, Ohtsuki and Mano (2020) found that one can determine phase diagrams in other disordered systems such as topological insulators and disordered Weyl semimetals (see corresponding entries in the encyclopedia). How other machine learning strategies such as unsupervised and reinforcement learning might add to the numerical approaches for Anderson localization is currently under much investigation.

Conclusion

In this entry to the encyclopedia, I have attempted to provide a very brief review of the rich variety of numerical algorithms developed to study Anderson localization. Due to brevity requirements appropriate for such an entry, details had to be mostly neglected. Still, with citations provided to hopefully the original publications as well as some recent examples, I hope that the reader can find enough information to get started with each approach and that seeing them in context allows for a considered choice of which method to use.

Acknowledgments

I am grateful for constructive suggestions on the manuscript by H. Fehske, E. Miranda, A. Rodriguez, T. Ohtsuki, L. Vidmar and J. Zakrzewski. Special thanks to E. Carnio for help with Fig. 4.

Abstract

Physics of itinerant electrons is governed by the combined effect of disorder and e-e interactions. Such systems display singular corrections in transport and thermodynamics and can be described in terms of a scale-dependent Fermi liquid. The metal-insulator transition (MIT) in the presence of interactions is a non-trivial example of a quantum phase transition. The dynamical exponent characterizing this transition is determined by a renormalization group equation. In two dimensions, the MIT can be discussed in terms of a flow in the disorder-interaction phase plane. The Wiedemann-Franz law holds for short range interactions, but is violated by the long-range Coulomb interactions.

Key points

- The analysis of the electron liquid in the presence of disorder focuses on diffusing electron-hole pairs.
- At low enough temperatures the resistance and the e - e scattering amplitudes acquire singular corrections, which are the more significant the stronger disorder is.
- The scheme most suitable for the analysis of the singular corrections arising in the system of diffusing electrons is the Renormalization Group (RG).
- The RG-analysis of the disordered electron liquid can efficiently be performed using the matrix Non-Linear Sigma Model (NLSM), which is a minimal functional that incorporates all essential degrees of freedom and symmetries.
- The metal-insulator transition (MIT) in a system of interacting electrons is an example of a quantum phase transition (QPT). The value of the dynamical scaling exponent which connects the spatial and energy scales in this QPT has to be calculated using a special RG-equation.
- The RG-flow captures both quantitatively and qualitatively the physics of the disordered two-dimensional electron liquid including the MIT.
- Similar to the electric conductivity, the thermal conductivity acquires a pronounced temperature-dependence at low temperatures, which can be analyzed with the NLSM extended to include gravitational potentials.

Introduction: Fermi-liquid in the presence of disorder

The original Fermi-liquid theory has been formulated by Landau (1956,1957) in terms of quasiparticles labeled with momenta $\mathbf{p}$, see in Lifshitz and Pitaevskii (1980). The most distinctive feature of a clean Fermi-liquid is a jump in the occupation number $n(\mathbf{p})$ at the Fermi-surface. Since in the presence of disorder the Fermi-surface is smeared, it may look as if the Fermi-liquid theory loses its applicability. This is, however, not completely correct. Elastic impurity scattering by itself does not generate electron-hole pairs and, therefore, some elements of the Fermi-liquid description are preserved even in the presence of disorder. The focus, however, shifts from quasiparticles toward diffusing electron-hole pairs. In Landau's microscopic theory of the clean Fermi-liquid the combination $\omega/(\omega - v_F \mathbf{n} \mathbf{k})$ is used as the dynamic part of the propagator of an electron-hole pair. This expression describes propagation of the pair along the direction $\mathbf{n}$, when the momentum difference of the two quasiparticles is $\mathbf{k}$, and the frequency difference is ω .

For large times, $t \gg \tau_{el}$, electrons have undergone many collisions with impurities; here, τ_{el} is the elastic mean free time for scattering from static impurities. Then, after averaging over the directions $\mathbf{n}$, the dynamical part of the electron-hole pair propagator acquires a diffusive form that after the analytical continuation to the imaginary frequency axis looks as follows:

$$\frac{\omega}{\omega - v_F \mathbf{n} \mathbf{k}} \Rightarrow \frac{\omega_n}{\omega_n + i v_F \mathbf{n} \mathbf{k}} \Rightarrow \frac{\omega_n}{\omega_n + D k^2}, \quad (1)$$

where $D = v_F^2 \tau_{el} / d$ is the diffusion coefficient for the spatial dimension d ; it is assumed that $1/\tau_{el} > D k^2$, ω , T . The resulting term in Eq. (1) describes the free diffusion of electron-hole pairs between acts of rescattering induced by the e - e interaction amplitude Γ^k . (Index k in Γ^k means that in the singular amplitude $\Gamma(\mathbf{k}, \omega)$ one first takes the limit $\omega = 0$ and only afterwards the limit $k \rightarrow 0$, i.e., Γ^k is static). In clean Fermi-liquids, because of the angular dependence of $\mathbf{n} \mathbf{k}$ in the denominator of the combination on the left hand side of Eq. (1), different angular harmonics Γ_l^k of the interaction amplitudes are coupled. On the contrary, in the presence of disorder only the zeroth harmonic of the interaction amplitude, $\Gamma_{l=0}^k$, is relevant for the rescattering of diffusing electron-hole pairs. All other harmonics with $l \neq 0$ are eliminated by random scattering of electrons caused by impurities. (This implies that the zero-sound modes predicted by Landau cease to exist in the presence of disorder.) As a result, the calculation of $\Gamma(\mathbf{k}, \omega)$ does not require the solution of an equation for the harmonics, but instead reduces to a simple summation of a geometric series. The process of rescattering is illustrated in Fig. 1.

The two-particle amplitude $\Gamma_{l=0}^k$ can be split into parts which can be classified according their spin structure:

$$\Gamma_{l=0}^{k \alpha_1 \alpha_2 \alpha_3 \alpha_4} = \frac{1}{2} \left[2 \tilde{\Gamma}_\rho \delta_{\alpha_1, \alpha_3} \delta_{\alpha_2, \alpha_4} + \Gamma_\sigma \vec{\sigma}_{\alpha_1, \alpha_3} \vec{\sigma}_{\alpha_2, \alpha_4} \right]. \quad (2)$$

Here, the singlet-channel amplitude $\tilde{\Gamma}_\rho$ controls propagation of the particle-number density $\rho(\mathbf{k}, \omega)$ in the singlet channel, $S = 0$, while Γ_σ controls the spin density, i.e., the triplet channel, $S = 1$.

A key point in studies of the true electron liquid, i.e., a quantum liquid with charged fermions, is the long-range character of the Coulomb interaction which requires special care. With this in mind, one has to identify terms in the interaction amplitude $\tilde{\Gamma}_\rho$ that carry information about the singular behavior of the Coulomb interaction at small momenta. (Graphically, these terms can be disconnected by cutting a single Coulomb interaction line, see Fig. 2.) The resulting amplitude of this part of the e - e interaction will be denoted as Γ_ρ^0 , while the remaining part of the interaction amplitude, which is irreducible with respect to the Coulomb interaction, will be denoted as Γ_ρ . The latter part describes the short-ranged part of the e - e interaction in the singlet channel that is not sensitive to the Coulomb singularity at small momenta. As a result, the amplitude $\tilde{\Gamma}_\rho$ has been split into two terms, $\tilde{\Gamma}_\rho = \Gamma_\rho^0 + \Gamma_\rho$.

To include dynamics in the ρ - and σ -density channels, one has to consider a ladder of either Γ_ρ - or Γ_σ -amplitudes alternating with dynamical electron-hole propagators. The resulting amplitudes $\Gamma_\rho(\mathbf{k}, \omega)$ and $\Gamma_\sigma(\mathbf{k}, \omega)$ acquire the form:

$$\Gamma_\alpha(\mathbf{k}, \omega) = \Gamma_\alpha \frac{D k^2 + \omega_n}{D k^2 + (1 - \Gamma_\alpha) \omega_n}, \quad \alpha = \rho, \sigma. \quad (3)$$

The position of the diffusion pole in $\Gamma_{\rho, \sigma}(\mathbf{k}, \omega)$ shifts as a result of re-scattering. This shift is the origin of the renormalization of the diffusion coefficients that is different in the ρ - and σ channels. The amplitudes $\Gamma_{\rho, \sigma}$ are related to the standard Landau parameters of Fermi liquid theory as $1 - \Gamma_\alpha = 1/(1 + F_0^\alpha)$.

In the analysis of the density-density correlation functions for a charged liquid, the focus of attention has to be directed toward the polarization operator $\Pi(k, \omega_n)$, which is the density-density correlation function *irreducible* with respect to the Coulomb interaction. The dynamical part of the polarization operator contains two “triangle” vertices γ^ρ separated by a ladder of dynamical

Fig. 1 Disordered Fermi-liquid: geometric series leading to Eq. (3) for $\Gamma(\mathbf{k}, \omega)$. Dashed lines symbolize the impurity scattering after averaging over a random disorder realization. In the framework of Fermi liquid theory only ladder-like processes are kept.

Fig. 2 On top: the screened Coulomb interaction. The triangular vertices γ^ρ are attached to the ending points of the interaction line. On the bottom: the short-range interaction amplitude in the singlet channel.

Fig. 3 Disordered Fermi-liquid: dynamical part of the polarization operator $\Pi(k, \omega_n)$.

electron-hole pair propagators, see Fig. 3. Both the left and right vertices γ^ρ are irreducible with respect to the dynamical sections. Collecting the static and dynamical parts of the polarization operator, one obtains Eq. (4b)

$$\Pi(k, \omega_n) = \Pi_{st} - 2v(\gamma^\rho)^2 \left[\frac{\omega_n}{Dk^2 + (1 - \Gamma_\rho)\omega_n} \right] \quad (4a)$$

$$\Rightarrow \Pi_{st} \frac{Dk^2}{Dk^2 + (1 - \Gamma_\rho)\omega_n}. \quad (4b)$$

In Eq. (4b), we have arrived at the canonical form for a correlation function of the density of a conserved quantity which must vanish in the limit $k \rightarrow 0$ when $\omega_n \neq 0$. This property must hold for any *conserved* quantity, as can be seen from the general form of a retarded correlation function

$$\chi(\mathbf{k}, \omega) = i \int_0^\infty dt e^{i\omega t} \langle [x(t), x(0)] \rangle_{\mathbf{k}}. \quad (5)$$

In the limit $k \rightarrow 0$ the densities $x(t)$ and $x(0)$ transform into the quantities $X(t)$ and $X(0)$, that are integrated over space. In the case when $X(t)$ is conserved in time, it obviously commutes with $X(0)$ at any moment. Consequently, $\chi(k \rightarrow 0, \omega)$ should vanish at any frequency.

One may rewrite the expression given in Eq. (4b) in a more conventional form corresponding to diffusion:

$$\Pi(k, \omega_n) = \Pi_{st} \frac{D_\rho k^2}{D_\rho k^2 + \omega_n}, \quad D_\rho = \frac{D}{1 - \Gamma_\rho}. \quad (6)$$

Here D_ρ is the diffusion coefficient of the particle-number density ρ . The next step which allows to find the electric conductivity is to relate $\Pi(k, \omega_n)$ to the current-current correlation function through the continuity equation $\partial \rho / \partial t + \nabla \cdot \mathbf{j} = 0$. Then, with the help of the Kubo formula, one can obtain the Fermi-liquid expression for the electric conductivity (e is electron charge):

$$\frac{\sigma_{charge}}{e^2} = \lim_{k \rightarrow 0} \frac{\omega_n}{k^2} \Pi(k, \omega_n) = \frac{\partial n}{\partial \mu} D_\rho = 2vD. \quad (7)$$

The above equation is nothing else but the Einstein relation for the electric conductivity $\sigma \equiv \sigma_{charge}$. It is worth emphasizing that the conductivity is determined by the product $(\partial n / \partial \mu) D_\rho$ (which is unquestionably positive) rather than a naïve $(\partial n / \partial \mu) D$. This point is very important in view of experimental measurements in heterostructures hosting a two-dimensional (2d) electron gas. In these systems, the electron gas is often under conditions when $\partial n / \partial \mu = (1 - \Gamma_\rho)$ becomes negative. However, for the conductivity the two negative renormalizations cancel each other out.

It remains to comment why the *irreducible* part of the density-density correlation function, $\Pi(k, \omega_n)$, rather than the full correlation function, has been used to find the conductivity. The terms that can be disconnected by cutting a single Coulomb line describe the rearrangement of the system in response to the external perturbation. The point here is that conductivity is a response to a resulting field acting on a charged electron. This resulting field is measured by a voltmeter as the difference in the electro-chemical potential. Thus, by keeping only terms that are irreducible with respect to the Coulomb interaction the rearrangement has been taken into account, and one can obtain the electric current in response to the actual field.

In the case when the total spin of conducting electrons is conserved, the scheme outlined above can be straightforwardly applied for the analysis of the spin-density correlation function. In the case of the spin density, the external vertices contain a spin operator $\sigma^x/2$ that corresponds to a probing magnetic field directed along the x -axis. These vertices are renormalized by the e - e interactions, and the corresponding renormalization factor is denoted below as γ^σ . In spite of this modification, all formulas for the spin-density correlation function $\chi_s^{xx}(k, \omega_n)$ are similar to those obtained in the case of $\Pi(k, \omega_n)$. The only change is the substitution of Γ_ρ by Γ_σ in the above expressions (correspondingly, one should replace $\gamma^\rho \rightarrow \gamma^\sigma$ and $\Gamma_\rho \rightarrow \Gamma_\sigma$ in Fig. 3).

The spin susceptibility χ_s determines the static limit of the spin-density correlation function $\chi_s^{xx}(k, \omega_n)$, just like $\partial n / \partial \mu$ determines the static limit of the polarization operator. As a result of the Fermi liquid corrections, $\chi_s \equiv \chi_s^{xx}(k \rightarrow 0, \omega_n = 0)$ is modified by the factor $(1 - \Gamma_\sigma)$ compared to $\chi_s^0 = (g_L \mu_B / 2)^2 2v$ for the clean Fermi gas (where g_L is the g-factor for the charge carriers), so that $\chi_s = \chi_s^0 (1 - \Gamma_\sigma)$. In the standard Fermi-liquid notation, $1 - \Gamma_\sigma = 1 / (1 + F_0^\sigma)$. Usually, F_0^σ is negative. Then, $(1 - \Gamma_\sigma)$ describes the Stoner enhancement of the spin susceptibility.

In the absence of magnetic impurities, i.e., when the total spin of conducting electrons is conserved, the sum of the static and dynamical parts acquires the structure already familiar from the calculation of $\Pi(k, \omega_n)$:

$$\chi_s^{xx}(k, \omega) = \chi_s \frac{D_\sigma k^2}{\omega_n + D_\sigma k^2}, \quad (8)$$

where $D_\sigma = D/(1 - \Gamma_\sigma)$. Hence, $(1 - \Gamma_\sigma)$ describes not only the Stoner enhancement of the spin susceptibility due to the e - e interaction, but also the suppression of the spin-diffusion coefficient $D_\sigma = D/(1 - \Gamma_\sigma)$.

In the case when the spin of conducting electrons is conserved, one may derive the Einstein-like relation for the spin conductivity following the route outlined previously for the electric conductivity, see Eq. (7):

$$\frac{\sigma_{spin}}{(g_L^0 \mu_B / 2)^2} = \frac{1}{(g_L^0 \mu_B / 2)^2} \lim_{k \rightarrow 0} \frac{\omega_n}{k^2} \chi_s^{xx}(k, \omega_n) = 2\nu D. \quad (9)$$

Taken together, Eqs. (7) and (9) reflect the fact that both the charge and the spin are carried by the same particles.

Up to now, averaging over disorder has been performed in a very particular fashion: within the framework of the Fermi-liquid theory, disorder has been considered only in the dynamical blocks describing diffusive propagation of electron-hole pairs interrupted by rescattering induced by the e - e interaction. This separation of the e - e interaction and disorder is the main approximation of the disordered Fermi-liquid theory. The content of this Section is a byproduct of a more general theory of the e - e interactions in disordered conductors developed by Finkel'stein (1983a, 1984a).

Beyond Fermi-liquid theory: Non-linear sigma model and scale-dependent theory of the disordered electron liquid

Matrix elements determining amplitudes of the e - e interaction, in fact, could be strongly modified by disorder, especially for states that are close in energy. Two examples showing how it works for effective amplitudes are presented in Fig. 4. The amplitudes are decorated by ladders of dashed lines which result *after averaging* over impurity scattering. Each of these ladders generates a diffusion propagator $1/(Dq^2 + \omega_n)$ and, consequently, is called “diffuson” (when the frequency is on the real axis, the retarded diffuson is equal to $1/(Dq^2 - i\omega)$); see Fig. 5. Diffusons, being singular, play a special role in modifying (renormalizing) the interaction amplitudes. As a result of the interplay of the interaction amplitudes and diffusons, the effective e - e interaction amplitudes in the diffusive regime, $1/\tau_{el} > T$, acquire corrections that are non-analytic in temperature T .

Besides the diffuson there is another mode, called the Cooperon, which also generates non-analytic corrections of *various* kinds (Gor'kov et al., 1979). This mode is a “cousin” of the diffuson, and it has the same diffusion propagator. The Cooperon represents a particle-particle pair with small total momentum propagating in a disordered environment, see Fig. 6. It is called the Cooperon, because of its relevance for the Cooper channel in which the superconducting instability develops.

The electric conductivity and, correspondingly, the diffusion constant D also acquire corrections that in the diffusive regime are non-analytic in temperature. Two diagrams illustrating the origin of corrections to D are shown in Fig. 7. In $d = 2$, *all* corrections both to the diffusion coefficient (electric conductivity) and the interaction amplitudes are logarithmically divergent in temperature, i.e., proportional to $\ln 1/T_{el}$. Logarithmic corrections to the conductivity caused by the e - e interaction were first obtained by Altshuler et al. (1980) and, conversely, to the interaction amplitudes themselves by Finkel'stein (1983a). In higher

Fig. 4 Examples of the e - e interaction amplitudes modified by disorder.

Fig. 5 Diffuson: propagators that capture the diffusive propagation of the electron-hole pairs at large time and length scales are called “diffusons”.

Fig. 6 Cooperon: disorder-averaged propagator of a particle-particle pair with small total momentum. The Cooperons capture the effects of quantum interference which lead to the weak localization corrections.

Fig. 7 Diagrams illustrating the origin of corrections to the diffusion constant D due to combined action of the e - e interactions and disorder.

dimensions, the problem becomes logarithmic near the MIT, Finkel'stein (1983b, 1984b), and Castellani et al. (1984a). (In the ballistic region, $T > 1/\tau_{el}$, non-analytic corrections due to the interplay of interaction and disorder also exist, Clarke et al. (2008). In $2d$, they are linear in temperature, when the disorder scattering is short-range.)

The divergent corrections signal the breakdown of the Fermi-liquid theory presented above. There is a need for resummation of the divergent terms using the Renormalization Group (RG) technique but, most importantly, there is a need to clarify the general structure of the theory. Objectives for RG analysis are as follows: At low enough energies, the e - e scattering amplitudes Γ_ρ and Γ_σ acquire corrections, which are the more significant the stronger disorder is. Conversely, resistivity - which is a measure of the effective strength of disorder - also acquires corrections which depend on the value of the interaction amplitudes. Hence, this problem calls for a scheme that can account for both effects in a consistent fashion. The RG-analysis is precisely such a scheme.

The RG-analysis for disordered conducting fermions can most efficiently be performed using the technique of the matrix Non-Linear Sigma Model (NLSM) originally introduced for non-interacting particles by Wegner (1979) and Efetov et al. (1980). In matrix terms, the disorder-averaged N -replica partition function of interacting electrons reads as follows:

$$\langle Z_N \rangle = \int dQ e^{-S[Q]}, \quad (10)$$

$$S[Q] = \frac{\pi\nu}{8} \int d^d r \text{Tr} \left[D(\nabla \hat{Q})^2 - 4z(\hat{\varepsilon} \hat{Q}) \right] - \frac{\pi\nu}{16} \int d^d r \left\{ \hat{Q}(\hat{\Gamma}_\rho^0 + \hat{\Gamma}_\rho) \hat{Q} + \hat{Q} \hat{\Gamma}_\sigma \hat{Q} + \hat{Q} \hat{\Gamma}_c \hat{Q} \right\}. \quad (11)$$

This functional is usually referred to as Finkel'stein's model, Finkel'stein (1983a, 1984a). The functional integration has to be performed over a matrix field $\hat{Q}$ within the manifold limited by the constraints: $\hat{Q}^2 = 1$, $\hat{Q} = \hat{Q}^\dagger$, and $\text{Tr} \hat{Q} = 0$. These constraints make the problem non-linear and also very non-trivial. The components of the matrix $\hat{Q}$ are defined as $Q_{n_1 n_2}^{ij, \alpha \beta}$, where n_1, n_2 are the Matsubara fermionic frequency indices with $\varepsilon_n = (2n + 1)\pi T$; i, j are the replica indices, and α, β include the spin and quaternion indices. The quaternion indices are needed to incorporate both the diffusons and Cooperons within one scheme. The replica limit, $N \rightarrow 0$, should be taken in order to perform the averaging over different realizations of disorder. The frequency matrix is $(\hat{\varepsilon})_{nm}^{ij, \alpha \beta} = \varepsilon_n \delta_{nm} \delta_{ij} \delta_{\alpha \beta}$. All the interaction terms are restricted by the energy and momentum conservation laws. (After averaging over disorder realizations, the resulting effective system is translation invariant: the scattering of the diffusion modes obeys the momentum conservation law.) The interaction terms are written symbolically, omitting such important details as the Pauli matrices acting in the spin and quaternion spaces which unify diffuson and Cooperon degrees of freedom in the Q matrices. Note that the ρ -term is split into two pieces as discussed above in connection with the polarization operator. The additional term $\hat{\Gamma}_c$ describes the e - e interaction in the Cooper channel.

The last point to be commented on is the parameter z introduced in front of the frequency matrix in the action $S[Q]$. For free electrons $z = 1$; also within the Fermi-liquid analysis of disordered electrons it remains equal to 1. When the theory is extended beyond the limits of the disordered Fermi-Liquid theory, z starts to acquire renormalization corrections. The parameter z gives the frequency renormalization in the propagators of the diffusons and Cooperons. Precisely owing to this parameter, the output of the RG-procedure is compatible with the charge- and spin-conservation laws. Moreover, z determines the relative scaling of the frequency with respect to the length scale and, thereby, it plays a central role in the critical region of the metal-insulator transition.

The saddle-point value of the matrix $\hat{Q}$, which is usually denoted as $\hat{\Lambda}$, is fixed by the frequency term $(\hat{\varepsilon} \hat{Q})$ in the above action; $\Lambda_{nm}^{ij, \alpha \beta} = \text{sign}(n) \delta_{nm} \delta_{ij} \delta_{\alpha \beta}$. It is clear that for small ε_n the fluctuating matrix $\hat{Q}$ is only weakly fixed to its equilibrium position and, correspondingly, fluctuations away from the equilibrium position are strong. To get some intuition, one may look on the NLSM for non-interacting electrons as a sort of the Heisenberg functional used in the theory of magnetism. Then, the frequency term in $S[Q]$ that breaks the symmetry with respect to the sign of the frequency is the counterpart of the external magnetic field. In this analogy, the diffusons and Cooperons are the counterparts of the magnons. The fluctuations of the $\hat{Q}$ -field are nothing else but the diffusons and Cooperons. The propagators of these two diffusion modes acquire the modified form $1/(Dk^2 + z\omega_n)$. They can be obtained by expanding the first two terms in $S[Q]$ up to quadratic order in $\delta \hat{Q} = (\hat{Q} - \hat{\Lambda})$.

The functional $S[Q]$ describes disordered interacting electrons with energies smaller than $1/\tau_{el}$. One may observe that the Fermi-liquid description of the disordered electron liquid presented in the previous Section can be reproduced by the quadratic expansion of the action $S[Q]$ in deviations of $\hat{Q}$ from its equilibrium value. Systems that principally differ from the disordered Fermi-liquid, e.g., electrons under the conditions of the quantum Hall effect, topological insulator surface states, graphene in the absence of the intervalley scattering, etc., contain a term in the action which leads to a topological protection. The coefficients in the

action $S[Q]$, e.g., the single-particle density ν , incorporate the Fermi-liquid renormalizations of the clean liquid as the input parameters. The RG-analysis covers energies between $1/\tau_{el}$ and the temperature. The disorder-averaged interaction amplitudes, the diffusion coefficient D as well as the parameter z are all scale-dependent at energies $\lesssim 1/\tau_{el}$. The renormalization corrections are determined by non-quadratic (i.e., anharmonic) terms in the action S . Note that the decoupling of different interaction channels occurs only on the level of the quadratic form of the action. During the course of the RG-procedure different channels, $\alpha = \rho, \sigma, c$, interfere. For example, in the diagram presented on the left side of Fig. 4, the amplitude Γ_ρ^0 is converted into Γ_σ as a result of scattering induced by disorder.

With the frequency renormalization parameter z included, the action $S[Q]$ preserves its form during the course of RG-transformations. With this at hand, the analysis of density-correlation functions of conserved quantities based on $S[Q]$ includes several steps: one needs to find (i) the RG-modified static part of the correlation function, and (ii) the renormalized triangle vertex, and then to obtain (iii) the dynamical part of the correlation function with the use of the quadratic expansion of the already renormalized action $S[Q]$. Performing these steps, one may observe that it is sufficient to substitute in all Fermi liquid expressions, starting from Eq. (3) till Eq. (8), the standard combinations $(1 - \Gamma_a)$ by the factors $(z - \Gamma_a)$ that also incorporate the renormalized values of the amplitudes Γ_a , Finkel'stein (1984a) and Castellani et al. (1984b):

$$\chi_a(k, \omega) = \chi_a^{static} \frac{D_a k^2}{\omega_n + D_a k^2}, \quad a = \rho, \sigma. \quad (12)$$

Here, $\chi_\rho^{static} = 2\nu(z - \Gamma_\rho)$ for the static part of the polarization operator, and $\chi_\sigma^{static} = \chi_\sigma^0(z - \Gamma_\sigma)$; the diffusion coefficients are both defined as $D_a = D/(z - \Gamma_a)$. It follows from Eq. (12) that the relation $\sigma/e^2 = 2\nu D$, see Eq. (7), still holds albeit with the value of D obtained from the RG procedure. The observation about equality of the charge and spin conductivities, $\sigma_{charge}/e^2 = \sigma_{spin}/(g_L \mu_B/2)^2$, also remains valid.

In the important case of the Coulomb interaction, the amplitude of the screened long-range interaction, Γ_ρ^0 , the short-range part of the interaction amplitude, Γ_ρ , and the parameter z are all renormalized in such a way that the resulting interaction amplitude acting in the ρ -channel is equal to z :

$$\Gamma_\rho^0 + \Gamma_\rho = z. \quad (13)$$

This result is of fundamental importance. It manifests that the theory of the electron gas interacting via the Coulomb interaction displays a high degree of internal symmetry. Pruisken and his coauthors connected this symmetry to a global symmetry of the problem which they called $\mathcal{F}$ -invariance (Pruisken et al., 1999), and which is intimately related to the gauge invariance.

Finally, it is useful to regroup the parameters of the functional S_Q by combining the frequency renormalization parameter z together with ν , Finkel'stein (1984a). Then, z acquires the physical meaning of a parameter renormalizing the density of states of the diffusion modes, while $D_Q = D/z$ can be interpreted as their diffusion coefficient:

$$\nu \Rightarrow z\nu, \quad D \Rightarrow D_Q = D/z. \quad (14)$$

As a result of regrouping, the interaction amplitudes always appear as Γ_a/z . Combining z with ν allows one to use dimensional arguments for expressions involving this parameter. It is natural to link $z\nu$ to the coefficient determining the specific heat c , Castellani and DiCastro (1986). Furthermore, the Einstein relation, the renormalized susceptibilities, as well as the diffusion coefficients describing the evolution of the charge- and spin-densities, all take a Fermi-liquid form albeit with renormalized coefficients which depend on the running scale of the RG procedure. For thermodynamics one gets

$$\chi_a^{static} = z\nu(1 - \Gamma_a/z)(\chi_a^0/\nu); \quad (15)$$

$$c/T = z\nu(c_0/T\nu); \quad (16)$$

and for transport quantities

$$D_a = D_Q/(1 - \Gamma_a/z), \quad a = \rho, \sigma; \quad (17)$$

$$\sigma/e^2 = 2(z\nu)D_Q = 2\nu D. \quad (18)$$

Here, χ_a^0/ν and $c_0/T\nu$ are constants, e.g., for the specific heat, $c_0/(T\nu) = 2\pi^2/3$.

Thus, the effective theory that adequately describes the problem of electrons diffusing in the random field of impurities is the NLSM with interactions. In fact, it is not a model, like the Landau's Fermi liquid theory is not a model. Independent of the assumptions used for the microscopical derivation of S_Q , it is a *minimal functional* which incorporates all essential degrees of freedom and symmetries of the disordered electron liquid. Magnetic impurities, external magnetic field, or spin-orbit scattering induce additional terms in the action $S[Q]$. These terms make some of the diffusion modes gapped. Then, a possible strategy is to preserve the general form of $S[Q]$ as given by Eq. (11), but to reduce the auxiliary matrix field $\hat{Q}$ to such a manifold that only singular diffusion modes remain, while all gapped modes will be excluded. Systems with different sets of singular fluctuation propagators (i.e., when the $\hat{Q}$ -fields are elements of different manifolds) belong to different universality classes. When only the fluctuations of density are important, such a system belongs to the so-called unitary class. The richest case is the orthogonal class in which fluctuations of the charge- and spin- densities as well as different kind of Cooperons are relevant. A system where spin-orbit

interaction reduces singular fluctuations to the charge-density mode and the singlet Cooperon belongs to the symplectic class. Naturally, the number of the e - e interaction terms involved in the action $S[Q]$ is different for different classes.

The symmetries encoded in the functional S_Q ensure its renormalizability. Correspondingly, during the course of the RG-procedure, the resulting theory of the disordered electron liquid preserves the structure of the Fermi-liquid theory, albeit with renormalized coefficients.

Scaling theory of the metal-insulator transition in $d = 2 + \epsilon$; role of the parameter z

In the dimension $d = 2 + \epsilon$ each *momentum integration* involving the diffusion propagators (see e.g., examples presented in Figs. 4 and 7) generates the dimensionless parameter

$$\rho = \frac{r_d(\lambda)}{2\pi^2/e^2} \propto \frac{e^2}{\sigma} \lambda^{d-2}. \quad (19)$$

Here ρ is equal to the resistance r_d of a d -dimensional cube of side length $\sim 2\pi/\lambda$ measured in units of $2\pi^2/e^2$; compared to the standard definition of the quantum resistance, this unit contains an additional factor π ; λ is the momentum cutoff which decreases during the renormalization; decreasing λ corresponds to enlarging blocks in the real-space renormalization procedure. Eq. (19) corresponds to Ohm's law with the conductivity σ depending on the scale λ .

It follows from the structure of the action $S[Q]$, when written with the help of Eqs. (13) and (14), that the RG-procedure can be performed in terms of the dimensionless resistance ρ and the reduced interaction amplitudes

$$\gamma_2 = -\Gamma_\sigma/z = \Gamma_2/z, \quad (20a)$$

(for repulsive interaction, $\gamma_2 > 0$) and

$$\gamma_c = \Gamma_c/z. \quad (20b)$$

With these variables, the set of the RG equations takes the general form:

$$d \ln \rho / dy = -\frac{\epsilon}{2} + \rho \beta_\rho(\rho; \gamma_2, \gamma_c; \epsilon), \quad (21a)$$

$$d\gamma_2 / dy = \rho \beta_{\gamma_2}(\rho; \gamma_2, \gamma_c; \epsilon), \quad (21b)$$

and also

$$d\gamma_c / dy = -\gamma_c^2 + \rho \beta_{\gamma_c}(\rho; \gamma_2, \gamma_c; \epsilon). \quad (22)$$

The right hand side of Eq. (22) starts from the γ_c^2 -term which describes the rescattering in the Cooper channel. In the case of attraction, $\gamma_c < 0$, this term is responsible for the superconducting instability at low temperatures. Generally, there is a competition between the γ_c^2 -term and β_{γ_c} which describes the suppression of the temperature of the superconducting transition by disorder. In amorphous films superconductivity can be *totally suppressed* by a moderate resistance per square, Finkel'stein (1987a).

The parameter z is described by a separate equation:

$$d \ln z / dy = \rho \beta_z(\rho; \gamma_2, \gamma_c; \epsilon). \quad (23)$$

The function β_z , as well as β_ρ and $\beta_{\gamma_2, \gamma_c}$ are all independent of z . In the above set of RG equations the logarithmic variable $y = \ln 1/[\max(D\lambda^2/z, \omega_n)\tau]$ has been used. This choice of the logarithmic variable is convenient because it allows us to take T as a natural lower cutoff; the upper cutoff is $1/\tau$. The explicit factor ϵ in the equation determining ρ originates from λ^{d-2} entering the definition of the RG-charge ρ . The concrete form of the functions $\beta_\rho, \beta_{\gamma_2}, \beta_{\gamma_c}, \beta_z$ depends on the universality class (i.e., the symmetry) of the system. In reality, the MIT in $3d$ is a difficult issue for analysis, because on its way to the MIT (e.g., as the temperature is lowered) the system may pass through a number of *crossovers* from one universality class to another.

In the case of a MIT, in Eq. (21a) the quantum corrections induced by the Cooperons (weak localization) and the ones appearing as a result of the interplay of the e - e interaction and disorder lead to an increase of the resistance as temperature decreases (i.e., $\beta_\rho > 0$, thus favoring localization), while the geometric factor ϵ competes with these corrections for $d > 2$. As a result, there is an unstable fixed point, $\rho = \rho_c$, which determines the critical behavior of the conductivity near the MIT.

Recall that while ρ is a constant at the point of the MIT, exactly at this point the conductivity vanishes at $T \rightarrow 0$. As it follows from Eq. (19), in the vicinity of the transition

$$\sigma(\lambda)/e^2 \propto \lambda^{d-2}. \quad (24)$$

In the $3d$ case, for example, on the metallic side of the transition the critical behavior develops in the region for which $1 \gg \lambda \gg \sigma(T=0)/e^2$. At non-zero temperature, in the critical regime of the MIT, the process of renormalization ceases at a scale where

$$D(\lambda)\lambda^2/z(\lambda) \sim T \xrightarrow{\text{using Eq.(18)}} \lambda^d/\nu \sim zT. \quad (25)$$

For the electric conductivity measured at external frequency $\omega \gg T$, the renormalization is cut off by ω rather than T . The above relations are a consequence of (i) the form of the diffusion propagator $\mathcal{D}(k, \omega_n) = 1/(Dk^2 + z\omega_n)$, and (ii) the definition of the RG-parameter g which exhibits a fixed point at the MIT. In addition, these relations take into account the result discussed in the previous section that (iii) all the renormalizations in between σ and D are canceled out: $\sigma/e^2 = 2\nu D$.

Thus, in order to find the temperature or frequency behavior of σ at the MIT, one has to connect the momentum and energy scales in the critical region, $\lambda \sim (z \max[\omega, T])^{1/d}$. However, z itself is a scaling parameter, see Eq. (23). Therefore, one needs to know the critical behavior of the parameter z at the transition, which is determined by the value of $\rho\beta_z$ at the critical point:

$$\tilde{\zeta} = -(\rho\beta_z)_{\text{critical point}}. \quad (26)$$

Correspondingly, the dynamical critical exponent connecting energy and momentum scales at the point of the MIT is

$$z_{\text{en/m}} = \frac{d}{1 + \tilde{\zeta}}. \quad (27)$$

For free electrons z is not renormalized, $\tilde{\zeta} = 0$, and at zero temperature $\sigma(\omega) \propto \omega^{1/3}$ for $d = 3$. The e - e interaction modifies this critical behavior of the conductivity through $\tilde{\zeta}$ which results in $z_{\text{en/m}} \neq d$ for the critical exponent, and

$$\sigma(\omega, T) \propto (\max[\omega, T])^{\frac{d-2}{z_{\text{en/m}}}} \propto (\max[\omega, T])^{\frac{d-2}{d}(1+\tilde{\zeta})}. \quad (28)$$

If $\omega \lesssim T$, the RG flow is cut off by the temperature, and

$$\sigma(T) \propto T^{\frac{d-2}{d}(1+\tilde{\zeta})}. \quad (29)$$

The scaling behavior described above suggests that the dependence of the conductivity on frequency and temperature can be described by a single function

$$\sigma(T, \omega)_{\text{critical}} \propto T^x f(\omega/T), \quad (30)$$

where $f(r) \rightarrow \text{const}$ when $r \rightarrow 0$, and $f(r) \propto r^x$ when $r \rightarrow \infty$, with $x = \frac{d-2}{z_{\text{en/m}}} = \frac{d-2}{d}(1 + \tilde{\zeta})$. This is a typical behavior near a quantum phase transition for which the MIT is, perhaps, a primary example. The outcome of the above discussion is quite general, and it does not depend on the specific details of the ϵ -expansion or any other approximation: the frequency or temperature behavior of the conductivity in the critical region of the MIT is determined by the right-hand side of the separate Eq. (23) at the fixed point of the transition, Finkel'stein (1983b, 1984b).

Experimentally, the study of the critical behavior of the MIT is a difficult task. A comprehensive discussion of experiments is beyond the scope of this article. Still a few comments seem to be appropriate here: (i) The dependence of σ on temperature in the critical region can be determined with a limited accuracy only. For the analysis of the critical behavior, the data should be taken outside the region of perturbative corrections, $\sigma(T) - \sigma(T=0) \gtrsim \sigma(T=0)$. On the other hand, one should remain within the quantum transport region, $\sigma(T) < \sigma_{\text{min}}$. (The Mott minimal conductivity σ_{min} is a scale separating regions where transport is dominated by classical or quantum mechanisms.) These two inequalities leave a limited window of $\sigma(T)$ appropriate for the analysis of the truly critical region of the MIT. (ii) The true critical behavior may be obscured by the so-called rounding of the transition, caused by an inhomogeneous distribution of dopants. Rounding may noticeably change the critical behavior, van Schaijk et al. (2000). (iii) It appears that "canonical" Si:P is not very suitable for studying the critical behavior at the MIT. The critical region is very narrow, and several different mechanisms interfere, Löneysen (2011). (iv) In measurements on the magnetic-field-induced MIT in GaAs and InSb semiconductors the critical behavior $\sigma(T) \sim T^{1/3}$ has been observed, Newson and Pepper (1986). In a persistent photoconductor, where the carrier concentration can be controlled very neatly, Katsumoto et al. (1987), $\sigma(T) \sim T^{1/2}$ at the transition, i.e., $x = 1/2$; this corresponds to $\tilde{\zeta} = 1/2$.

On the theoretical side, the problematic feature of the flow equations given by Eqs. (21a) and (21b) is that the amplitude γ_2 in the absence of spin scattering (i.e., in the case of the orthogonal class) diverges at a finite scale, Finkel'stein (1984c), and thereafter the RG-calculation becomes uncontrolled. The peculiar point here is that together with the divergency of γ_2 the diffusion coefficient $D_\sigma = D/(z + \Gamma_2) \rightarrow 0$. This allows to suggest that on the metallic side of the MIT there is a finite region of concentrations where the fluctuations of the spin density are already localized, while the charge density fluctuations remain itinerant. There is a number of scenarios related to the divergence of γ_2 . In particular, the question of a possible transmutation of the spin diffusion modes into local ones near the MIT in 3d still remains unresolved. An interesting observation here is that the width of the Electron Spin Resonance line $\Delta H_{1/2}$ (i.e., the rate of relaxation) in uncompensated Si:P with $n/n_c = 1.09$ and 1.25 appears to be *exactly proportional* to the spin susceptibility χ when the temperature is below 1 K, Paalanen et al. (1986). Presumably, the MIT in uncompensated Si:P differs from that in the compensated semiconductors by generating local spin modes at low enough energies in a region near the transition, Finkel'stein (1987b). The discussed divergence in the spin-density channel at a finite scale may well be a driving force for the formation of local spin modes at the corresponding scale. Whether they will reveal themselves as the Kondo effect or somehow differently remains unclear, and it may depend on whether the semiconductor is compensated or not.

The conductivity is usually fitted by

$$\sigma(T)_{\text{critical}} \propto T^x f_t(|t/t_c - 1|/T^y), \quad (31)$$

where t is the tuning parameter. It is assumed that in the limit $u \rightarrow 0$, the function $f_t(u) \rightarrow \text{const}$, and $\sigma(T) \propto T^x$ at the transition. In the opposite limit $u \rightarrow \infty$, i.e., at lowest temperatures, $f_t(u) \propto u^{x/y}$. This implies that $\sigma \rightarrow |t/t_c - 1|^{x/y}$ and, thereby, the critical exponent $\mu = x/y$. In this analysis, a fit with the same parameters x and y can be performed on both sides of the MIT, metallic and insulating. As a byproduct of such a study, the fact that the MIT is indeed a quantum phase transition can be confirmed.

As a tuning parameter t , the concentration of dopants, magnetic field (Khmel'nitskii and Larkin, 1981), or intensity of light in the case of persistent photoconductor can be used. The neutron-transmutation-doping (NTD) method allows researchers to fabricate samples with completely homogeneous doping in order to avoid rounding of the transition. Studies of the disorder driven MIT in NTD Ge:Ga uncompensated and compensated semiconductors reveal a very interesting and rich picture, Itoh et al. (2004). It was found that in non-compensated Ge:Ga at $B = 0$ in a very narrow region of dopant concentrations, $(n_c - n)/n_c \lesssim 1\%$, the critical exponent is $x = 0.38$. However, when the MIT was tuned by a magnetic field, $B \neq 0$, a successful fit with the exponent $x = 0.5$ can be performed in a broad region of magnetic fields. Finally, for the compensated samples in the absence of a magnetic field, $B = 0$, the exponent is $x = 0.33$.

Measurements of the AC conductivity, $\sigma(\omega)$, are, unfortunately, very rare. For example, the temperature and frequency dependences were studied simultaneously in amorphous niobium-silicon alloys (Nb:Si). The one-to-one correspondence between the T - and ω -dependent conductivities was observed at compositions near the MIT, Lee et al. (2000), thus confirming the above picture of the MIT as a quantum phase transition. The critical exponent x has been found to be equal to $1/2$ for this system which corresponds to $z_{\text{en/m}} = 2$, i.e., $\sigma(T, \omega)_{\text{critical}} \propto T^{1/2} f(\omega/T)$, see Eq. (30).

Another important consequence of the general structure of the RG-equations which describe the critical region of the MIT concerns thermodynamics. From the very fact that the critical region is determined by the fixed point of Eqs. (21a), (21b), and (22), it follows that the only parameter which continues to evolve when changing the scale during the course of the RG is the parameter z . Since z is directly related to the renormalization of the effective density of states of the diffusion modes, it follows immediately from Eqs. (15) and (16) that the critical temperature dependence of thermodynamic quantities at the MIT is described by the same dynamical critical exponent $z_{\text{en/m}}$. For the specific heat, for example, $c \propto T^{d/z_{\text{en/m}}}$.

The content of this section may look like a simple dimensional analysis. In fact, it heavily relies on the structure of the theory described by the NLSM with interaction terms. In this context, the parameter z plays a special role. Since this parameter is responsible for the frequency renormalization of the diffusion propagators, it is of particular importance for finding the correct form of the density and spin-density correlation functions. Furthermore, the form of the density correlation function dictated by the particle number conservation allows one to obtain the Einstein relation for the electric conductivity. Only with the information about the structure of the theory at hand, the critical behavior near the MIT can be found by a straightforward dimensional analysis.

In conclusion, the metal-insulator transition in a system of diffusing electrons is an example of a *quantum phase transition*, Sachdev (2011), with a dynamical scaling exponent $z_{\text{en/m}}$ controlled by the parameter z . Precisely the same parameter describes the scaling behavior of both the conductivity and thermodynamic quantities in the critical region of the MIT. In the critical region, the scaling dependence of the parameter z on the temperature or frequency is described by the critical exponent ξ . The structure of the theory is very general and is not related to the ϵ -expansion which can be used for the approximate calculation of the value of ξ for different classes of universality. The appearance of a finite critical exponent $\xi \neq 0$ is a direct consequence of the e - e interaction, and it takes different values for systems belonging to different universality classes. The value of ξ and, correspondingly, of the dynamical scaling exponent $z_{\text{en/m}}$ cannot be postulated from general principals, but has to be calculated based on Eq. (26) at the fixed point controlling the MIT.

Tunneling density of states

The tunneling density of states (TDOS) or, as it is also called, the single-particle density of states, $\nu(\varepsilon)$, exhibits a rather pronounced critical behavior in the vicinity of the MIT. This quantity can be obtained by measuring the differential conductance $G_j(V)$ of a tunneling junction at a finite voltage bias V : $G_j(V) \propto \nu(\varepsilon = V)$. In the early theory of the MIT by McMillan (1981), when the parameter z was yet not identified, the TDOS was erroneously treated as the parameter connecting the length and energy (or frequency) scales that provides a dynamic critical exponent. In fact, the TDOS is not a part of the RG-scheme. The TDOS is defined as

$$\nu(\varepsilon) = -\frac{1}{\pi} \text{Im} \int \mathcal{G}^R(\varepsilon, \mathbf{p}) \frac{d\mathbf{p}}{(2\pi)^d}. \quad (32)$$

As such, this quantity is not gauge invariant, and it can be changed by a time-dependent gauge transformation. Thereby, it cannot enter the RG-scheme which operates only with truly gauge-invariant quantities. Moreover, with the use of the $\hat{Q}$ -technique, $\nu(\varepsilon)$ can be expressed as a diagonal component of the averaged product of the two matrices:

$$\nu(\varepsilon)/\nu = \left\langle \hat{\Lambda} \hat{Q} \right\rangle_{\varepsilon\varepsilon}, \quad (33)$$

However, the presence of $\hat{\Lambda}$ in its explicit form (rather than as in the form of matrix $\hat{Q}$) indicates that the corresponding quantity has potential complications related to gauge-invariance.

The combined effect of Coulomb interaction and disorder leads to a strong suppression of the TDOS. This observation explains the so-called zero-bias anomaly in the tunneling spectra of disordered systems (Altshuler and Aronov, 1979). Compared to other effects related to the interplay of the e - e interaction and disorder, corrections to the TDOS are the strongest. In particular, in two-dimensions the *perturbative correction* obtained in the lowest order in ρ appears to be log-squared rather than just logarithmic:

$$\nu(\varepsilon)/\nu = 1 - \frac{\rho}{4} \ln(1/|\varepsilon|\tau) \ln(\tau\omega_0^2/|\varepsilon|). \quad (34)$$

Here $\omega_0 = D\kappa_{scr}^2$, while κ_{scr} is the inverse of Thomas-Fermi screening radius.

It follows from Eq. (33), that by measuring the TDOS one studies how an ε -component of the matrix $\hat{Q}$ fluctuates around its equilibrium position as a consequence of the e - e interaction. In the absence of the e - e interaction, there are no such fluctuations, and the TDOS $\nu(\varepsilon)$ is equal to ν . To go beyond the perturbative correction, a comparison with the physics of phonons is instructive. Measurement of a tunneling current is a kind of “Mössbauer experiment” which determines the effect of the zero-point fluctuations of the electromagnetic field on the effectiveness of tunneling. Indeed, it has been recognized already in the early studies (Finkel’stein, 1983a) that the calculation of $\nu(\varepsilon)$ is very similar to the calculation of the Debye-Waller factor, and can be reduced to a *Gaussian integration* with respect to the fields describing deviations of the matrix $\hat{Q}$ from $\hat{\Lambda}$. Correspondingly, in order to obtain a non-perturbative result, the perturbative correction to the TDOS should be exponentiated:

$$\nu(\varepsilon)/\nu \propto \exp \left[-\frac{\rho}{4} \ln(1/|\varepsilon|\tau) \ln(\tau\omega_0^2/|\varepsilon|) \right]. \quad (35)$$

The presence of the log-square corrections to $\nu(\varepsilon)$ when $d = 2$ leads to the fact that the ε -expansion of the critical exponent of the TDOS starts from a constant, Finkel’stein (1984b). The reason is that at $d = 2 + \epsilon$ in the exponent of Eq. (35), the factor $1/\epsilon$ replaces one of the two logs and cancels a factor ϵ coming from the charge $\rho_c \propto \epsilon$.

The log-square corrections in the TDOS are specific for the long-range Coulomb interaction only. In a model description, when the dynamically screened Coulomb interaction $V_C(k, \omega_n)$ is replaced by a constant, such corrections cannot arise. Furthermore, the log-squared corrections cancel out when calculating any other physical quantities, except the TDOS.

The TDOS is often erroneously considered as the effective density of states in the presence of the e - e -interaction. In fact, the TDOS is a very peculiar quantity: by fabricating a counter-electrode for the tunneling junction, one creates a reference point which allows to study the effect of long-range fluctuations of the electric potential on the tunneling conductivity. While giving rise to log-squared corrections to the TDOS, these fluctuations do not contribute to other physical quantities. For example, this type of correction does not influence the temperature of the superconducting transition T_c (i.e., a quantity, which is very sensitive to the density of states at the Fermi energy ν). All log-squared corrections to T_c are canceled out, Finkel’stein (1988).

The MIT in a two-dimensional system

In the 2d-geometry, extensive measurements can be performed using the same sample. By applying a gate voltage, it is possible to vary broadly the density of electrons confined within the 2d-channel inside a MOSFET device. When the density of electrons is high, the level of disorder is, effectively, small. Conversely, when the density is low, the electrons are at a strong level of disorder. Thus, one can pass from a metallic to an insulating behavior by varying the gate voltage, which is a big advantage of working with 2d systems. It has been found in Si-MOSFETs that on the metallic side of the transition the resistance $\rho(T)$ at low enough temperatures drops noticeably as the temperature is lowered further. Since (i) the resistance for a moderate strength of disorder drops at low temperatures, while (ii) the resistance indisputably increases when disorder is strong, it is therefore *unavoidable* that the MIT exists somewhere in-between, at least in n -(001) silicon inversion layers.

An important observation in Si-MOSFETs is that in a relatively broad region on the metallic side of the MIT $\rho(T)$ is non-monotonic; it increases before dropping down as the temperature is lowered. The non-monotonic behavior of $\rho(T)$ points toward the existence of a *competition* between different mechanisms. Any “universal” theory of the MIT in dilute 2d electron systems that employs only one parameter cannot succeed in describing a system with a non-monotonic temperature dependence. The value of the critical resistance at which the transition occurred was found to be the same for devices fabricated even from different wafers, although the critical density at the MIT was sample dependent, see Fig. 3 in Kravchenko and Sarachik (2004). This fact points toward universality. One, therefore, has some reasons to apply the approach based on the RG-analysis of the NLSM, if the conducting electrons are degenerate and within the diffusive regime, i.e., $T \ll 1/\tau_{el} \lesssim \varepsilon_F$. The 2d electron gas in Si-MOSFETs, which in fact is only a moderately high-mobility system, is *unique* in the sense that the scattering is mostly short-range, so that the MIT indeed occurs in the diffusive regime. (The smoothness of the disorder may drive a system with a high-mobility directly from the ballistic regime to the insulating phase.)

The boundary of the diffusive regime can be determined from measurements of the in-plane magnetoconductivity. The spin-splitting induced by the in-plane magnetic field suppresses the effectiveness of the spin-density fluctuations that results in a negative magnetoconductivity, [Lee and Ramakrishnan \(1982\)](#). In the diffusive regime, for $b = g_L \mu_B B / k_B T \ll 1$

$$\Delta\sigma = -(e^2/\pi h) K_v C_{ee}(\gamma_2, \rho) b^2. \quad (36)$$

Here $K_v = n_v^2$; the conduction band in an n -(001) silicon inversion layer has two almost degenerate valleys, i.e., in Si-MOSFET $n_v = 2$. At not too strong disorder C_{ee} depends only on the interaction amplitude, $C_{ee} = 0.091\gamma_2(\gamma_2 + 1)$. By contrast, at higher temperatures, or at higher density, when electrons are ballistic, $\Delta\sigma \propto (T\tau)b^2$. Thus, by studying the temperature dependence of the magnetoconductivity, one may chart the region where the electrons are diffusive and, furthermore, extract the temperature dependence of the amplitude γ_2 which appears as a result of the logarithmic corrections. Proceeding in this way, it has been found that the diffusive regime in Si-MOSFETs extends up to a few Kelvin in a density range around the critical density of the MIT. The corresponding Fermi temperature is of the order of 10 K and, therefore, electrons are already degenerate at temperatures convenient for measurements.

In the one-loop order, the pair of coupled RG equations describing the evolution of the resistance and the amplitude γ_2 with temperature takes the form, [Punnoose and Finkel'stein \(2002\)](#):

$$\frac{d \ln \rho}{dy} = \rho [n_v + 1 - (4n_v^2 - 1)\Phi(\gamma_2)], \quad (37)$$

$$\frac{d\gamma_2}{dy} = \rho \frac{(1 + \gamma_2)^2}{2}. \quad (38)$$

These equations obtained in the lowest order in ρ incorporate the full dependence on the e - e amplitudes. In the first equation, the combination $(4n_v^2 - 1)$ is the number of spin-valley multiplet channels, while the standard combination $\Phi(\gamma_2) = \frac{1 + \gamma_2}{\gamma_2} \ln(1 + \gamma_2) - 1$ was first time obtained by [Finkel'stein \(1983a\)](#) for $n_v = 1$. The factor n_v in the square brackets corresponds to the weak-localization (Cooperon) corrections and, finally, the factor 1 entering the square brackets is the contribution of the long-ranged Coulomb singlet-amplitude (after dynamical screening) and is, therefore, universal. Next, it should be noted that the factor 1 appearing in Eq. (38) for γ_2 also originates from the Coulomb singlet-amplitude combined with scattering induced by disorder.

The following salient features of the RG-flow described by Eqs. (37) and (38) should be noted: While the amplitude γ_2 increases monotonically as the temperature is reduced, the resistance has a very special non-monotonic form changing from insulating behavior ($d\rho/dT < 0$) at high temperatures to metallic behavior ($d\rho/dT > 0$) at low temperatures. The non-monotonic behavior of the resistance as a function of the temperature results from a competition between the charge-density diffusion modes and the Cooperons, on the one hand, and the fluctuations of the spin- (and valley-) degrees of freedom, on the other hand. The former favor localization, while the latter act against it, thus stabilizing the metallic state at low enough temperatures, with a change of the trend in $\rho(T)$ at an intermediate temperature. The two equations act in a tandem: resistance increases the amplitude γ_2 . This increasing amplitude in its turn changes the trend in $\rho(T)$.

For $n_v = 1$ the change in the slope of $\rho(T)$ occurs at $\gamma_2 = 2.08$, whereas for $n_v = 2$ the combination $(4n_v^2 - 1)$ considerably increases the effectiveness of anti-localization, so that passing through the maximum in $\rho(T)$ happens at a considerably smaller value $\gamma_2 = 0.45$. It follows from the general form of Eqs. (37) and (38), that the ratio $\rho(T)/\rho_{\max}$ is equal to a universal function, once the logarithmic variable η_T is introduced: $\rho(T)/\rho_{\max} = R(\eta_T)$, where the logarithmic variable $\eta_T = \rho_{\max} \ln(T/T_{\max})$, and $\rho_{\max}$ is the value of $\rho(T)$ at its maximum.

The description provided by the RG equations (37) and (38) has been confirmed by the analysis of the experimental data for a moderate strength of disorder i.e., in the region of applicability of the one-loop approximation. The fit of the resistance curves with a single universal function $R(\eta)$ captured in the correct temperature intervals the non-monotonic behavior of $\rho(T)$ together with its drop by a factor of five and the subsequent flattening, [Punnoose and Finkel'stein, 2002](#). The full temperature dependence of the resistance is completely controlled by its value $\rho_{\max}$ at the maximum; there are no other fitting parameters. Not too close to the MIT, the extracted values of $\gamma_2(T_{\max})$ at which $\rho(T)$ passes through the maximum was found ([Anissimova et al., 2007](#)) equal to 0.45 as predicted by the theory for $n_v = 2$. A similar analysis of the data obtained in devices fabricated from another wafer was given by [Knyazev et al. \(2006\)](#).

Since the one-loop calculation, which is valid for a moderate strength of disorder, gives a *drop* of the resistance at low temperatures, and the localization at strong disorder is indisputable, the conclusion about the existence of the MIT can be justified even within the one-loop approximation. Starting from the 1980s, it had been commonly assumed that electrons in 2d are "eventually" (i.e., at $T = 0$ always localized, [Abrahams et al. \(1979\)](#)). In view of the anti-localization effect of the e - e interactions, this point of view had to be radically altered.

As it has been already discussed in connection with Eqs. (21a) and (21b), the problematic feature of the flow equations given by Eqs. (37) and (38) is that the amplitude γ_2 diverges at a finite temperature T^* and thereafter the RG-calculation becomes uncontrolled. Fortunately, the scale T^* decreases very rapidly with n_v as $\ln \ln(1/\tau T^*) \sim (2n_v)^2$, making the problem of the divergence of γ_2 irrelevant for all practical purposes even for $n_v = 2$. At $n_v \rightarrow \infty$, the theory becomes internally consistent: $T^* \rightarrow 0$.

Obviously, in spite of the success in the description of Si-MOSFETs at a moderate disorder, the *single-curve* (universal) solution $R(\eta)$ cannot provide a description of the MIT. To approach the critical region of the MIT, the disorder has to be treated beyond the lowest order in ρ , while adequately retaining the effects of the interaction. A theory of the MIT, based on a two-loop calculation, was

Fig. 8 The resistance-interaction flow diagram of 2d electrons in a Si-MOSFET device. The circle indicates the location of the quantum critical point from which the three separatrices emanate. The arrows shown on the separatrices indicate the direction of the flow as the temperature is lowered. The electron densities are given in units of 10^{10} cm^{-2} . The interaction amplitude in the spin-density channel is represented by the coefficient C_{ee} , which was extracted from the magnetoresistance. *Inset:* The resistance-interaction ($t-\Theta$) flow diagram obtained in the two-loop calculations. Area (1) is the metallic phase, which is stabilized by the interaction. Area (2) is the insulating phase where disorder prevails. Area (3) is the region of strong spin correlations (not accessible in this device).

developed by Punnoose and Finkel'stein (2005) using the number of identical valleys as a large parameter, $n_v \rightarrow \infty$. The valley degrees of freedom are akin to flavors in standard field-theoretic models. It is natural, working in the large- n_v approximation, to introduce the amplitudes $\Theta = 2n_v\gamma_2$ together with the resistance parameter $t = n_v\rho$. The parameter t is thus the resistance per valley, $t = 1/[(2\pi)^2 vD]$. Both quantities Θ and t remain finite in the large- n_v limit.

The resulting resistance-interaction ($t-\Theta$) flow diagram is plotted as an inset in Fig. 8. It contains the quantum critical point, which corresponds to the fixed point of the equations describing the evolution of t and Θ . Crossing the attractive separatrix by changing the initial values of t and Θ (e.g., by changing the carrier density) leads to the MIT. In the main panel of Fig. 8 the two-parameter scaling theory has been verified experimentally by Anissimova et al. (2007). In this plot, the coefficient C_{ee} effectively represents the interaction amplitude in the spin-density channel. It has been extracted by fitting $\Delta\sigma(B, T)$ to Eq. (36), which allows to obtain the RG-evolution of C_{ee} as a function of temperature. A number of curves with a non-monotonous temperature dependence of $\rho(T)$ in the metallic region are clearly visible there. The flow diagram presented in Fig. 8 confirms all the qualitative features of the theoretical predictions. The possibility of presenting the data as a flow diagram gives a very strong argument in favor of the two-parameter scaling theory in Si-MOSFETs.

To conclude, the high-mobility samples of Si-MOSFETs provide an ideal playground to study the properties of a 2d disordered electron liquid and, in particular, Anderson localization in the presence of the $e-e$ interactions. The RG-theory gives not only a qualitative but (within the region of its applicability) also a quantitative description of the experimental data in these systems. The two-parameter RG-theory of the disordered electron liquid captures both quantitatively (for moderate disorder) and qualitatively the physics of the two-dimensional disordered liquid in the diffusive regime. A quantum critical point separates the metallic phase, which is stabilized by electronic interactions, from the insulating phase, where disorder prevails over the electronic interactions. The possibility of presenting the data as a flow diagram is a strong argument in favor of the applicability of the two-parameter scaling theory in Si-MOSFETs.

Thermal conductivity

The thermal conductivity κ characterizes the heat current $\mathbf{j}_Q$ flowing through a material in response to a temperature gradient, $\mathbf{j}_Q = -\kappa \nabla T$. In a Fermi liquid at low enough temperatures, the inelastic scattering rate for particles near the Fermi energy is small, the thermal conductivity is primarily determined by disorder scattering, and the Wiedemann-Franz law (WFL) $\kappa = \mathcal{L}_0 \sigma T$ with $\mathcal{L}_0 = \pi^2/3e^2$ holds. In the disordered electron liquid, disorder scattering and interactions become strongly intertwined. Their

interplay leads to renormalizations of transport coefficients and thermodynamic susceptibilities. A question of fundamental importance for understanding the scale-dependent Fermi liquid theory addressed in this Section is how the renormalizations affect the thermal conductivity, and if they can lead to a violation of the WFL.

It is convenient to discuss the thermal conductivity using the NLSM formalism in the Keldysh technique, rather than in the Matsubara formalism. In the Keldysh technique, the action is defined on the Keldysh contour which contains the forward (+) and backward (−) paths, see e.g., [Kamenev \(2011\)](#). The thermal conductivity can be extracted from the retarded heat density correlation function defined as $\chi_k(x_1, x_2) = -i\theta(t_1 - t_2) \langle [\hat{k}(x_1), \hat{k}(x_2)] \rangle_T$, where $\hat{k} = \hat{h} - \mu\hat{n}$ is the heat density operator, $\hat{h}$ is the Hamiltonian density operator, $x = (r, t)$, and the angular brackets denote thermal averaging.

Introducing fields on the forward (+) and backward (−) paths of the Keldysh contour, one may define the classical (cl) and quantum components (q) of the heat density symmetrized over the two branches of the contour, $k_{cl/q} = \frac{1}{2}(k_+ \pm k_-)$. The RG-analysis, including effects of the spin density fluctuations, has been reproduced in the Keldysh technique by [Schwiete and Finkel'stein \(2014a\)](#). For thermal transport, this scheme has to be extended by adding the source term $S_\eta = 2 \int x [\eta_2(x) k_{cl}(x) + \eta_1(x) k_q(x)]$ to the microscopic action, where η_1 and η_2 are the so-called gravitational potentials, [Luttinger \(1964\)](#). With these terms, one can find χ_k by differentiation the partition function, $\chi_k(x_1, x_2) = (i/2)\delta^2 \mathcal{Z} / \delta \eta_2(x_1) \delta \eta_1(x_2)$. Finally, the thermal conductivity κ can be extracted from the disorder-averaged correlation function $\langle \chi_k(x_1, x_2) \rangle_{dis} = \chi_k(x_1 - x_2)$ ([Castellani et al., 1987](#)) as follows:

$$\kappa = -\frac{1}{T} \lim_{\omega \rightarrow 0} \lim_{k \rightarrow 0} \left[\frac{\omega}{k^2} \text{Im} \chi_k(k, \omega) \right]. \quad (39)$$

A serious complication arises when working with the gravitational potentials introduced via term $S_\eta : \eta_1, 2$ couple (among other terms) to the random disorder potential u_{dis} . Fortunately, one can release the disorder term from the explicit dependence on the gravitational fields with the transformation $\psi \rightarrow \hat{\lambda}^{1/2} \bar{\psi}, \bar{\psi} \rightarrow \bar{\psi} \hat{\lambda}^{1/2}$, where $\hat{\lambda} = 1/(1 + \eta_1 \hat{\sigma}_0 + \eta_2 \hat{\sigma}_1)$ and $\hat{\sigma}_0$ and $\hat{\sigma}_1$ are Pauli matrices in Keldysh space. From here on, the NLSM in terms of the Keldysh $\hat{Q}$ -matrices can be derived along standard lines. In the Keldysh NLSM, $\hat{Q}_{ee'}$ generally depends on both frequency arguments. The metallic saddle point $\hat{Q}_{sp} = \hat{\sigma}_3$, where $\hat{\sigma}_3$ is also Pauli matrix in the Keldysh space. The temperature of electrons enters through the distribution function encoded in $\hat{u}$,

$$\hat{u}_e = \begin{pmatrix} 1 & \mathcal{F}_e \\ 0 & -1 \end{pmatrix}, \quad \mathcal{F}_e = \tanh \left(\frac{\varepsilon}{2T} \right). \quad (40)$$

Matrices $\hat{u}$ decorates the $\hat{Q}$ -matrices as follows: $\hat{Q}(\varepsilon\varepsilon') = \hat{u}_e \hat{Q}_{ee'} \hat{u}_{e'}$.

The static part of the heat density correlation function is related to the specific heat c as $\chi_k^{static} = -cT$, while the specific heat can be found from the average heat density as $c = \partial_T \langle \hat{k} \rangle_T$. The average value of $\langle \hat{k} \rangle_T$ can be obtained by differentiating the partition function with respect to the gravitation source η_2 . Then, the analysis of the diffusion modes part of the specific heat together with the fermionic part c_0 allows to reproduce the conclusion ([Castellani and DiCastro, 1986](#)) that in the disordered electron liquid as a result of renormalizations $c = zc_0$.

For finding the thermal conductivity, it is enough to know the dynamical part of the heat density correlation function χ_k^{dyn} , see Eq. (39). For the analysis of χ_k^{dyn} , it suffices to keep terms up to linear order in the gravitation potentials in the NLSM action by expanding $\hat{\lambda} \approx 1 - \eta_1 \hat{\sigma}_0 - \eta_2 \hat{\sigma}_1$. Since the RG flow for D, z , and the interaction amplitudes Γ_ρ and Γ_σ is known, it remains to determine vertex corrections by studying the renormalization of the gravitation source field $\hat{\eta}$. The NLSM extended by the gravitational potentials has the following (symbolic) form, [Schwiete and Finkel'stein \(2014b\)](#):

$$S_\zeta = \frac{\pi v i}{4} \int d^d r \text{Tr} \left[D \left(1 + \hat{\zeta}_D \right) (\nabla \hat{Q})^2 + 2iz \left\{ \hat{e}, 1 + \hat{\zeta}_z \right\} \delta \hat{Q} \right] - \frac{\pi v}{8} \sum_{n=1}^2 \int d^d r v \left\{ \delta \hat{Q} \left(1 + \hat{\zeta}_{\Gamma_n} \right) \hat{\Gamma}_n \delta \hat{Q} \right\}, \quad (41)$$

where $\hat{\zeta}_X(\mathbf{r}, \varepsilon + \omega, \varepsilon) = \zeta_X(\mathbf{r}, \omega)$ for $X \in \{D, z, \Gamma_1, \Gamma_2\}$ represent the gravitational potentials (it is convenient here to work with the interaction amplitudes $\Gamma_1 = (\Gamma_\rho - \Gamma_\sigma)/2$ and $\Gamma_2 = -\Gamma_\sigma$); here, $\delta \hat{Q} = \hat{Q} - \hat{\sigma}_3$ and $\delta \hat{Q} = \hat{u} \delta \hat{Q} \hat{u}$. The initial conditions for the gravitation potential are: $\zeta_z = \zeta_{\Gamma_1} = \zeta_{\Gamma_2} = -\eta_1$, $\zeta_D = 0$. We see from Eq. (41), that there are vertices related to frequency and interactions. Besides, the potential ζ_D was introduced to anticipate the possibility that the sources ζ_X with $X \neq D$ migrate to the D -term during the RG procedure.

The final result of the RG-analysis acquires a very compact form, [Schwiete and Finkel'stein \(2014b, 2014c\)](#):

$$\Delta(X_{i_0} \zeta_{i_0}) = \sum_{j=1}^4 \zeta_j \frac{\partial}{\partial X_j} (\Delta X_{i_0}), \quad (42)$$

where ΔX symbolizes a logarithmic correction to X . The result holds for all $X \in \{D, z, \Gamma_1, \Gamma_2\}$ (In Eq. (42), the notation ζ_i and X_i with $i = 1 \dots 4$ is used). The result presented in Eqs. (42) bears a certain resemblance with the multiplicative RG ([Bogoliubov and Shirkov, 1959](#)), because the source terms enter in combination with the charges X in a multiplicative way. One can show, using Eqs. (42) in combination with the known structure of the RG equations that the parameters ζ_X do not flow, provided that initially $\zeta_D = 0$ holds

Fig. 9 The dynamical part of the heat density-heat density correlation function. As discussed in the main text, no additional rescattering induced by the e - e interactions occurs.

and all remaining $\zeta_{X \neq D}$ are equal to each other. Thus, there exists a fixed point for the gravitational potentials in the multi-parametric RG-flow of the functional S_ζ . This remarkable balance between the different terms in S_ζ ensures the conservation of energy during the course of the RG-procedure.

After all renormalizations, the dynamical part χ_{kk}^{dyn} is determined by the averaged product of η_1 - and η_2 -frequency terms that can be calculated in the ladder approximation, see Fig. 9. The interaction vertices are not effective at this final stage, because such contributions have already been accounted for during the RG procedure. Finally, the dynamical part of the correlation function takes the form $\chi^{dyn}(k, \omega) = -c_0 T (\gamma_z^k)^2 i\omega / (Dk^2 - i\omega)$. Overall, the heat density correlation function is obtained by adding the static and dynamical parts as

$$\chi_k(k, \omega) = -cT - c_0 T z^2 \frac{i\omega}{Dk^2 - i\omega} = -cT \frac{D_Q k^2}{D_Q k^2 - i\omega}. \quad (43)$$

In these equations, the relation $c = zc_0$ for the renormalization of the specific heat has been used. With the help of Eq. (39), the thermal conductivity is found as $\kappa = cD_k = c_0 D$. While the diffusion of heat is governed by the heat diffusion coefficient $D_Q = D/z$, the frequency renormalization z cancels out when calculating the thermal conductivity. As an immediate consequence of this observation in combination with the RG-result for the conductivity, $\sigma = 2e^2 v D$, the WFL $\kappa/\sigma = \pi^2 T / 3e^2 = \mathcal{L}_0 T$ holds even in the scale dependent disordered electron liquid, Castellani et al. (1987) and Schwiete and Finkel'stein (2014b).

So far, the calculation of the thermal conductivity described above is based on a model with Fermi-liquid type interactions. The inclusion of Coulomb interactions into the RG analysis affects the results for both electric and thermal conductivities, but leaves the Wiedemann-Franz ratio $\kappa/\sigma T$ unchanged. However, the long-range character of the Coulomb interaction and the constraints imposed by gauge invariance require special care, Catelani and Aleiner (2005) and Schwiete and Finkel'stein (2016a). For example, in the case of $2d$ conducting electrons, while electrons are confined within a conducting plane or thin film, the electric field and its energy density extend over the whole $3d$ space.

Owing to long range part of the Coulomb interaction, additional logarithmic corrections to the thermal conductivity without analog for the electric conductivity arise in $2d$ from a sub-temperature energy range. Consequently, the WFL is violated in the presence of Coulomb interactions. Because of the additional logarithmic corrections, the calculation of thermal conductivity demands a two-stage procedure: the leading logarithmic corrections originating from energies in the RG-interval $(1/\tau, T)$ can be absorbed into the scale-dependent RG charges of the extended NL σ M. Once all RG-corrections are taken into account, one may find the sub-temperature correction using parameters determined by the current scale of the RG procedure. The structure of the heat density correlation function, Eq. (43), remains intact. The only modification is the diffusion coefficient, $D \rightarrow \tilde{D} = D + \delta D$, where D includes the RG-corrections and δD originates from the sub-thermal processes. The correction to the thermal conductivity from sub-thermal energies is equal to

$$\delta\kappa = \frac{T}{12} \log \frac{D\kappa_{scr}^2}{T}. \quad (44)$$

The correction $\delta\kappa$ presented in Eq. (44) was obtained perturbatively by various techniques (Raimondi et al., 2004; Niven and Smith, 2005; and Catelani and Aleiner, 2005). The two-stage procedure described above generalized these calculations by showing that all Fermi-liquid and RG renormalizations (including the parameter z) drop out when calculating Schwiete and Finkel'stein (2016b).

The correction $\delta\kappa$ causes a violation of the WFL. For a detailed discussion of the violation of the WFL, it is useful to introduce the "thermal resistance" $\rho_k \equiv (\mathcal{L}_0 T / \kappa) e^2 / 2\pi^2$, for which the relation $\rho_k = \rho$ holds as long as the WFL is satisfied. The dimensionless function $R_k(\eta_T) = \rho_k(\eta_T) / \rho_{max}$ is the thermal analog of universal function $R(\eta_T)$ discussed in the previous section. While the solution of the RG equations (37) and (38) depends on n_v , the number of valleys does not affect the correction. Hence, the relative weight of the WFL-violating correction is n_v -dependent. For an arbitrary n_v , $R_k(\eta_T)$ can be parametrized as (Schwiete and Finkel'stein, 2016b)

$$R_k(\eta_T) = \frac{R(\eta_T)}{1 + R(\eta_T) (P_{max} - \frac{1}{2} \eta_T)}, \quad (45)$$

where $P_{max} \equiv (1/2) \rho_{max} \log (D\kappa_{scr}^2 / T_{max}) = [\rho_{max} - \rho_k(0)] / \rho_k(0)$ is a measure for the violation of the WFL law at the temperature T_{max} . Remarkably, the maximum of $R_k(\eta_T)$ is positioned at a universal value (independent of P_{max}), determined by the condition $(\partial_{\eta_T} R) / R^2 = 1/2$. For $n_v = 2$, this gives $\eta_{T,k}^{max} \approx -0.0785$; examples of curves with $P_{max} = 0.2, 0.3$ and 0.4 are shown in Fig. 10.

To conclude, for short-range interactions of the Fermi liquid-type, the WFL displays a remarkable robustness, and the low-temperature corrections to thermal conductivity are parallel to those for the electric conductivity. In contrast, for a generic electron liquid with long-range Coulomb interactions, there exist delocalizing contributions to the thermal conductivity that do not

Fig. 10 “Thermal resistance” R_k and resistance R in dimensionless units for $n_v = 2$. R_k coincides with R if the WFL holds. The parameter P_{max} is a measure for the violation of the WFL law at the temperature T_{max} . In the discussed theory, the maxima of R_k are shifted from the maximum of R by a value that is independent on P_{max} . The high temperature-regime for which $R_k > R$ is unphysical.

have any analog for the electric conductivity. They are beyond the RG approach, originate from scattering processes with very low energy-transfer of the order of the temperature, and lead to a violation of the WFL.

Conclusion

The physics of itinerant electrons is determined by the combined effect of disorder and e - e interactions. Together, they generate a rich set of non-trivial phenomena. There are singular corrections to various quantities, both in transport and thermodynamics, which need to be summed in order to obtain the resulting behavior. The metal-insulator transition (MIT) gives a non-trivial example of a quantum phase transition (QPT). The dynamical scaling exponent needs to be found from a separate RG equation, rather than being postulated heuristically. In two-dimensional systems, the physics is determined by the RG-flow in the disorder-interaction plane. The flow is governed by a fixed point and associated separatrices. Crossing the separatrix implies the MIT. In thermal transport, the long-range part of the Coulomb interaction causes a violation of the Wiedeman-Franz law.

On the methodological side, the problem of disordered interacting electrons is an impressive example of the effectiveness of field-theoretical methods in condensed matter physics. In particular, the effect of correlations in the originally fermionic problem is entirely described in terms of fluctuations of the Q-matrices in the NLSM functional.

Abstract

Semiconductor alloys are at the heart of many optoelectronic devices. Among these alloys there are many prominent materials in which the virtual crystal approximation breaks down, including both highly-mismatched alloys such as $\text{GaAs}_{1-x}\text{N}_x$, and also the III-N alloys, $(\text{Al,Ga,In})\text{N}$, where the difference in energy gap between InN and AlN is more than twice that between any of the more conventional III-V alloys. For such alloys one needs to describe the electronic structure taking atomic-scale disorder effects explicitly into account. Density functional theory can give some insight, but the limited supercell size that can be treated imposes artificial long-range ordering that can give misleading results. This has mandated the development of predictive empirical atomistic methods such as tight-binding and empirical pseudopotential models for large-scale calculations to quantitatively predict electronic and optical properties. Such atomistic models are, however, computationally too expensive for full device simulation, which then requires continuum models. But conventional continuum models are not sufficiently accurate for many disordered systems. Various quantum approaches have therefore been developed to overcome this challenge. These include explicitly incorporating random composition fluctuations into one- or multi-band $k\cdot p$ models, or the explicit introduction of localized states in the Hamiltonian, giving a band-anticrossing model to describe, e.g., the impact of N resonant defect levels on the band structure of $\text{GaAs}_{1-x}\text{N}_x$. Device simulations based, e.g., on the drift-diffusion model require semi-classical approaches that quantitatively treat disorder. We describe how the recently developed localization landscape method is addressing this question. Having overviewed the impact of disorder, we exemplify its effects by considering III-N alloys and heterostructures, where disorder effects play an increasingly important role as one moves from $(\text{Al,Ga})\text{N}$ to $(\text{In,Ga})\text{N}$ and then to $(\text{Al,In})\text{N}$.

Key points

- Disorder effects are critical for the electronic and optical properties of key semiconductor alloys.
- Different scales of calculation—from *ab-initio* quantum to disordered semi-classical—required to analyze material and device properties.
- Localized defect states can strongly impact in extreme alloys.
- Novel approaches such as the localization landscape method allow quantitative simulation of disordered alloy systems.

Introduction to basics of simulations and carrier localization effects in semiconductor materials

Introduction

Advanced optoelectronic devices rely on the epitaxial growth of heterostructures, utilizing a combination of different semiconductor materials. Using ternary or even quaternary alloys in the active region of a device, one of the main aims is to tune the emission wavelength of the system to the desired region. For many III-V alloys, formation of an alloy only introduces weak disorder, and it remains possible to describe the band structure using what is referred to as the *virtual crystal approximation* (VCA), where for instance one treats each group III atom in gallium aluminum arsenide ($\text{Ga}_{1-x}\text{Al}_x\text{As}$) as a weighted average of a Ga and an Al atom. However,

when bringing different materials together in an alloy, the electronic structure might be more dramatically changed than one would expect from a simple linear interpolation of the material parameters of the involved components. From a fundamental physics viewpoint, this is often related to the fact that the replaced anion or cation species is much bigger or smaller in size than its “substitute”. Also, differences in electronegativity have to be considered when predicting electronic and optical properties of the alloy. A well-known example in which a simple electronic structure description fails is the dilute nitride (N) system $\text{GaAs}_x\text{N}_{1-x}$ (O'Reilly et al., 2009). When a single N atom replaces an As atom in GaAs, it forms a resonant defect level (localized state) above the conduction band edge of GaAs (Wolford et al., 1984a; Liu et al., 1990). Conventional alloy models cannot describe the electronic structure of such an *extreme alloy*, and other approaches must be employed. To account at least in part for some of the localization effects, simplified *band-anticrossing (BAC) models* have been established to capture key features in the electronic structure of such systems (O'Reilly et al., 2009).

Carrier localization effects can be observed in many systems. For instance, when looking at (In, Ga)N alloys, one is replacing Ga atoms by much larger In atoms. The situation is even more extreme for (Al, In)N alloys in terms of the atomic sizes. In analogy to the dilute N case, one could expect carrier localization effects in III-N systems. Experimental observations give clear indications of localization effects in III-N alloys. For example, using positron annihilation measurements, Chichibu et al. (2006) demonstrated the presence of carrier localization effects in nitride-based alloys. Further clear experimental evidence of localization phenomena has been given by optical measurements, such as photoluminescence (PL) spectroscopy studies (Chichibu et al., 1999; Morel et al., 2003; Graham et al., 2005; Hammersley et al., 2012; Marcinkevičius et al., 2013).

Here, we focus our attention on theoretical methods to describe quantitatively carrier localization effects in semiconductor materials and heterostructures, taking as example both dilute nitride and III-N alloys. We overview advantages and shortcomings of some of the different approaches used to address this question. Furthermore, we highlight some of the outcomes of these theoretical studies, confirming for instance the presence of localized states in nitride-based alloys and their importance for an accurate modeling of their electronic and optical properties. Overall, it is important to note that while on the experimental side, localization features in semiconductor alloys have been observed and discussed widely, a detailed theoretical investigation of these effects started only recently.

We therefore present here an overview of different theoretical approaches to address the electronic structure of semiconductor materials, describing how these different models can account for alloy fluctuations and thus carrier localization effects. Key models include density functional theory, continuum-based models and semi-empirical atomistic frameworks. In general, several features and aspects of disordered alloys and related heterostructures are still not well understood and here we point out some of these open questions taking as primary example localization features in (In, Ga)N, (Al, In)N and (Al,Ga)N systems. We conclude with a summary of our analysis and key perspectives for the future.

Theoretical approaches to address carrier localization effects in semiconductor alloys and related heterostructures

Despite clear experimental evidence, potential carrier localization effects due to alloy fluctuations have been widely ignored in the theoretical modeling of III-V and III-N alloys, heterostructures and devices. Systems such as wurtzite (In, Ga)N/GaN-based quantum wells (QWs) have been largely treated as homogenous, one-dimensional structures which can be described by averaged material parameters. It is only in the last few years that more sophisticated theoretical studies have been performed. Several approaches have been taken to gain insight into electronic and optical properties of disordered semiconductor alloys, related heterostructures and optoelectronic devices. These include first-principle density functional theory, (modified) continuum-based approaches, and semi-empirical atomistic models. Modified continuum approaches include the band-anticrossing model used to describe extreme alloys such as $\text{GaAs}_x\text{N}_{1-x}$, as well as the localization landscape approach employed to take account of disorder effects when undertaking semi-classical simulations of disordered structures, and in particular for understanding the impact of alloy fluctuations on the carrier transport in light-emitting diodes (LEDs).

However, before focusing on the different approaches in detail, we consider some of the particularities of III-N alloys, to highlight why one faces considerably different challenges in the modeling of such disordered systems when compared to other more “classical” III-V materials, e.g. (In,Ga)As or (Al,Ga)As alloys. One of the main differences between, for instance, (In,Ga)As and III-N systems is that the latter is usually grown in the hexagonal wurtzite phase; (In,Ga)As preferentially grows in the cubic zincblende phase. This change in the crystal structure has a range of relevant consequences. For example, it leads to the situation that wurtzite III-N systems exhibit a so-called *spontaneous built-in electric polarization vector field* (Bernardini et al., 1997). This quantity, due to the symmetry of the underlying zincblende lattice, is not present in (In,Ga)As systems (Bernardini et al., 1997). This spontaneous polarization vector field is a constant field along the wurtzite *c*-axis, which is usually the standard growth direction of III-N heterostructures. Thus, when growing heterostructures where in general the involved materials exhibit different spontaneous polarization vector fields, from basic electrostatics one expects an electrostatic built-in field in these systems. Consequently, in a GaN/(Al,Ga)N QW system polarization charge densities at the interfaces between the material systems GaN and (Al,Ga)N are expected. These polarization charges result in an electrostatic built-in field (Im et al., 1998). A schematic illustration of the situation is given in Fig. 1 (left) where it can be seen that the field gives rise to a spatial separation of the charge carriers in a QW structure, with

Fig. 1 (left) Schematic illustration of the spontaneous polarization vector fields ($\mathbf{P}^{\text{spon}}$) and the connected interface polarization charges in a *c*-plane GaN/AlN quantum well. (b) Consequence of the electrostatic built-in field for electron (ψ_1^e) and hole (ψ_1^h) ground states; Solid black lines indicate conduction and valence band edges in a *c*-plane system.

electrons pulled to the upper interface of the heterostructure and holes to the lower interface in Fig. 1 (right). This built-in field does not directly lead to localization effects, but, as we discuss below, can have impact on the analysis of localization effects.

In addition to the spontaneous polarization vector field, there is also a strain induced, so-called *piezoelectric polarization vector field* present in III-N materials (Bernardini et al., 1997). This feature is further enhanced by the large lattice mismatch between the binary materials InN, GaN and AlN. For instance, the lattice mismatch between InN and GaN is approximately 10–11%; between InN and AlN it is around 14–15%. Taking all these aspects into account, electrostatic built-in fields of the order of MV/cm have been reported in the literature (Im et al., 1998; Simon et al., 2003).

Additionally, the large lattice mismatch and thus strain fields also give rise to the question how local strain effects and connected built-in potential contributions affect the electronic structure. Further, given the big difference in atom size for example between In, Ga and N atoms, the question arises as to how local In—N—In chains embedded in GaN affect the electronic structure of (In,Ga)N alloys. Similar questions are relevant when considering the substitution, e.g., of As atoms by N atoms in GaAs_xN_{1-x}.

Taking all these effects into account, an accurate theoretical modeling of the electronic structure of disordered III-V and III-N materials presents significant challenges, especially when compared to more conventional (In,Ga)As systems. Thus, in general one faces in a first step the question of how to calculate the electronic structure of disordered systems. To this end we will introduce methods that range from first-principle calculations up to semi-empirical models. We start in the next section with the “exact” solution of the Schrödinger equation to predict the band structure of a semiconductor material, which leads us to *density functional theory*.

Density functional theory

When looking at the number of valence electrons that contribute to the bonding in each cubic centimeter of a material, one ends up with around 10^{23} valence electrons. Thus, when calculating the electronic structure of a solid, in general a complex many-body problem must be solved, given that the energy and the wave function of each electron depends on those of all other electrons. To find for instance the ground state energy, E_{GS} , of the electronic system under consideration, the full *time-independent Schrödinger equation* of a complex N -particle many-body system needs to be solved. Obviously, this is a highly non-trivial problem. The basic idea of *density functional theory* (DFT) is now, instead of calculating the antisymmetric ground state wave function $\Psi_{\text{GS}}(\mathbf{r}_1, \dots, \mathbf{r}_N)$, one investigates the corresponding electron charge density $\rho_{\text{GS}}(\mathbf{r})$. The benefit of studying $\rho_{\text{GS}}(\mathbf{r})$ instead of $\Psi_{\text{GS}}(\mathbf{r}_1, \dots, \mathbf{r}_N)$ is that, while $\Psi_{\text{GS}}(\mathbf{r}_1, \dots, \mathbf{r}_N)$ depends on three spatial coordinates per particle, $\rho_{\text{GS}}(\mathbf{r})$ depends only on three spatial variables since it is a collective quantity.

Hohenberg and Kohn (1964) were able to prove that the ground state energy E_{GS} of a many-particle system is an unambiguous functional of the ground state electron density $\rho_{\text{GS}}(\mathbf{r})$. But even though the Hohenberg-Kohn approach provides a general framework, it does not immediately give the form of the different functionals, e.g., how the kinetic energy depends on $\rho_{\text{GS}}(\mathbf{r})$. This was solved in a second step by Kohn and Sham in 1965 by introducing a scheme that gave rise to an effective single-particle equation in which a particular part of the effective potential, namely the *exchange-correlation part*, requires approximations (Kohn and Sham, 1965). The derived effective single-particle Schrödinger equation is known as the *Kohn-Sham equation*.

For practical calculations within the framework of the Kohn-Sham equations, information about the form of the exchange-correlation functional is required. For this quantity one must rely on approximations. One of these approximations, which is still widely used, is the so-called *local density approximation* (LDA) (Kohn and Sham, 1965; Martin, 2011), whereby an inhomogeneous system is locally described by a homogenous electron gas. While this is a crude approximation, it works remarkably well for many systems and properties but systematically fails for others (Perdew, 1985; Cohen et al., 2012). The underestimation of the band gap energy of semiconductors and insulators is probably one of the best-known problems of LDA (Perdew, 1985). Looking at the III-N systems, LDA fails completely for InN with its small band gap (Moses et al., 2011), and predicts it to be a metal. Therefore, when interested in optical properties of narrow gap systems, LDA-DFT suffers from significant shortcomings.

For this reason, modified and improved DFT approaches have been used by different groups around the world to overcome the shortcomings of the LDA-DFT approach. One scheme that has become very popular is the use of *screened hybrid functional approaches*, for instance, the *Heyd-Scuseria-Ernzerhof (HSE)* ansatz (Heyd et al., 2003). In such an ansatz, Hartree-Fock theory is combined with local exchange correlation functionals in which the so-called *exact exchange mixing parameter* α can also be used as an adjustable parameter (Moses et al., 2011; Heyd et al., 2003). These hybrid functionals are a step forward in comparison to local functionals and have been widely used for semiconductor materials since they can provide, in contrast to LDA-DFT, very good descriptions of the bulk band gaps. For instance, with standard settings of HSE-DFT calculations (HSE06 functionals), the band gap of InN is 0.66 eV, which is in good agreement with experimental data (0.6–0.7 eV) (Moses et al., 2011).

Such a DFT approach allows in general for an accurate description of the electronic band structure over the entire *first Brillouin zone*. Additionally, it can treat semiconductor alloys on a microscopic level, allowing therefore to study any given alloy on an atomistic level. However, this high accuracy, first-principle approach comes also at the cost of high computational demands. Compared to LDA-DFT, the computational demands of hybrid-functional calculations are significantly higher (Pela et al., 2015). Thus, within these *ab-initio* approaches, supercells of a several hundred up to a few 1000 atoms can be treated. Standard calculations rely probably on 64–128 atom supercells. Therefore, with these methods fundamental bulk properties of alloys can ideally be studied. But, when it comes to carrier localization features in realistic QW systems, where not only the active region (e.g. (In,Ga)N) has to be considered but also the barrier material (e.g., GaN), the simulation system size can reach easily several tens of thousands of atoms. This is beyond most of the current DFT implementations. Thus, more empirical methods are required.

Given that many alloy systems are direct band gap materials, of particular interest for optoelectronic devices is the band structure around $\mathbf{k} = \mathbf{0}$, the Γ -point. The behavior of the highest valence and lowest conduction bands at the boundaries of the first Brillouin zone is of secondary importance for the optical properties of these systems. Building on the aspect that only a particular part of the first Brillouin zone is relevant for optical properties, more empirical methods have been developed over the years to describe the band structure accurately in the region of interest. These models are computationally less demanding and due to their semi-empirical nature, they can overcome for instance the band gap problem of standard LDA-DFT calculations. Obviously, given that they are computationally relatively cheap, these methods are highly attractive for calculations of electronic and optical properties of semiconductor heterostructures and devices. In the next sections the basic concepts of these methods are reviewed, starting with the so-called (*multi-band*) *k-p-method*, which can be classified in general as a continuum-based approach.

Continuum-based approaches

When modeling the electronic structure of electronic and optical devices, one is generally interested in the region near the band gap E_g , which is defined as the energetic separation between the highest filled valence (bonding) band state and the lowest empty conduction (anti-bonding) band state. Fig. 2 shows schematically the band structure of GaN close to the energy gap, where the lowest energy state in the conduction band, E_c is at the Γ -point ($\mathbf{k} = \mathbf{0}$). Since E_c is directly above the highest energy state in the valence band, E_v , GaN is called a *direct band gap semiconductor*. To provide a continuum description of the band structure of a system

Fig. 2 Schematic illustration of a bulk band structure in III-N nitride materials, including group theoretical classification of the different conduction (Γ^c) and valence (Γ^v) bands.

near $\mathbf{k} = 0$ for direct band gap materials, the $\mathbf{k}\cdot\mathbf{p}$ approach is a widely used ansatz (Chuang and Chang, 1996; Winkelkemper et al., 2006; Marquardt et al., 2012; Yang et al., 2014). In general this method is based on perturbation theory and requires the exact energy levels to be known near $\mathbf{k} = 0$. More details about the underlying theory can be found in several books, for instance, in Refs. Lew Yan Voon and Willatzen (2009) and O'Reilly (2002) and we will not give here all the mathematical aspects.

To establish a $\mathbf{k}\cdot\mathbf{p}$ model, it requires an accurate description of the lowest conduction band and the highest valence bands. A similar approach is taken for zincblende and wurtzite structures. It can be seen from Fig. 2 that the valence band structure presents a more complicated situation compared to the conduction band. This stems from the fact that from an atomistic point of view the conduction band is mainly described by an s-like state while the valence band states in both wurtzite and zincblende structures are mainly p-like in character near the valence band edge. Therefore, in the case of the valence band, the “Bloch” wave functions are made up of p_x , p_y and p_z -like atomic orbitals which all contribute to the valence band states. Fig. 2 consequently shows three bands near the valence band maximum. The first two bands are so-called *heavy-hole* (HH) and *light-hole* (LH) bands, or sometimes A- and B-bands. They receive their names from the fact that the energy of the HH band varies at a slower rate when moving away from $\mathbf{k} = 0$ than in the case of the LH band. The third band in a wurtzite structure is usually denoted as the *crystal field split-off* (CF) or C-band. The energetic position of this band with respect to the A- and B-bands is dependent on the nitride material in question. For InN and GaN, the C-band lies energetically below the A- and B-band (Vurgaftman and Meyer, 2003). For AlN the C-band sits energetically above the other two bands (Vurgaftman and Meyer, 2003). The position of the band is connected to the so-called *crystal field splitting energy*, which is positive in InN and GaN and negative in AlN (Vurgaftman and Meyer, 2003). The valence band ordering has implications for the polarization properties of the emitted light.

$\mathbf{k}\cdot\mathbf{p}$ methods can be at different levels of sophistication, basically depending on the number of bands included in the description. The number of explicitly included bulk bands in the model also gives the name of the multi-band Hamiltonian (Harrison, 2005). One of the most widely used models for analyzing the band structure of wurtzite III-N systems is the 8-band model by Chuang and Chang introduced in Ref. Chuang and Chang (1996). It accounts for the three valence bands and the (energetically lowest) conduction band. Since the model takes the electron spin into account, each band is two-fold degenerate. Thus, eight bands are considered in the description. Likewise, an 8-band $\mathbf{k}\cdot\mathbf{p}$ model can be used to describe the doubly degenerate lowest conduction and three highest valence bands in zincblende materials. However, it should be noted that often reduced versions of this approach are employed for studying the band structure of wurtzite or zincblende heterostructures. An example is the single-band effective mass approximation, where only the conduction and the A-band are included in the calculation for GaN, for instance. These bands are then even separately treated, thus neglecting valence band conduction band coupling effects. A detailed overview of different types of multi-band $\mathbf{k}\cdot\mathbf{p}$ models is given for example in the textbook by Lew Yan Voon and Willatzen (2009).

These models are extremely popular to describe the electronic and optical properties of semiconductor heterostructures. Overall, the benefit of this approach is that it is computationally extremely cheap, at least when compared to DFT. Thus, QW and quantum dot (QD) structures of realistic size and shape can be addressed. Additionally, these models are parameterized in terms of bulk material parameters such as effective masses, band gaps, etc. near the Γ -point for instance. So once the composition dependence of the different quantities is established, the model can be easily applied to different systems. However, here the drawback of the method becomes apparent. Since the whole approach relies on macroscopic bulk parameters, the method, at least in its standard 1-, 4-, 6- or 8-band description, is not sensitive to the underlying microscopic crystal structure in terms of different atomic positions in an alloy. Thus, when looking for example at (In,Ga)N/GaN QW structures with 25% In content, the QW region is described by a Hamiltonian H with effective parameters, which have been interpolated between the parameters of GaN and InN in a particular way (linearly, quadratic, etc.). Thus, QWs are in general described as an ideal one-dimensional problem along the growth direction. In the in-plane direction, the QW is still perfectly periodic and thus states can be characterized by an in-plane wave vector $\mathbf{k}_{||}$. But, if carrier localization effects are introduced by random alloy fluctuations, the continuum-based $\mathbf{k}\cdot\mathbf{p}$ method intrinsically is not designed to address this question, at least on a microscopic level and in its “standard” form described above. Nevertheless, different groups have introduced modified continuum-based models to account for alloy fluctuations and thus connected carrier localization effects as we will see below.

Band-anticrossing model

One of the most useful modified models is the band-anticrossing (BAC) model to describe the electronic structure of extreme alloys such as $\text{GaAs}_x\text{N}_{1-x}$. It is well-established that when a single N atom replaces an As atom in GaAs, it forms a resonant defect level above the conduction band edge (CBE) of GaAs (Liu et al., 1990; Wolford et al., 1984b). This defect level arises because of the large difference in electronegativity and atomic size between N and As (Vogl, 1984; Hjalmarson et al., 1980; Lindsay and O'Reilly, 2003). The BAC model introduced by Walukiewicz and co-workers explains the extreme band gap bowing observed in $\text{Ga}_{1-y}\text{In}_y\text{N}_x\text{As}_{1-x}$ in terms of an interaction between two levels, one at energy E_N associated with these localized N impurity states ψ_N , and the other at energy E_c associated with the extended CBE state ψ_{c0} of the (Ga, In)As matrix, with the two states linked by a matrix element V_{Nc} describing the interaction between them (Shan et al., 1999). The conduction band dispersion of $(\text{Ga, In})\text{N}_x\text{As}_{1-x}$ is then given in the BAC model by the lower eigenvalue of the determinant

$$\begin{vmatrix} E_N - E & V_{Nc} \\ V_{Nc} & E_c + \frac{\hbar^2 k^2}{2m_c^*} - E \end{vmatrix} \quad (1)$$

where m_c^* is an appropriately chosen band edge effective mass for the (Ga,In)As host matrix material. The measured variation of band gap with N composition, x , is then very well described using the BAC. The BAC model has therefore proved very useful in the design and analysis of optoelectronic devices containing (Ga,In)(N,As) and other extreme alloys.

In practice however, replacing As by N introduces a range of N-related defect levels, associated with isolated N atoms, N-N pairs and larger clusters of N atoms. The effect of such defect levels on the alloy conduction band structure is strongly dependent on the relative energy of the distribution of defect levels and the host CBE. Overall, the BAC model therefore provides a good qualitative explanation of the electronic properties of dilute nitride and other extreme alloys. However, it is in many cases necessary to include detail of the distribution of N-related defect levels to obtain a quantitative understanding of the conduction band structure and of localization effects in dilute nitride alloys.

Composition fluctuations and localization landscape approach

For III-N systems, probably one of the first works into the direction of treating carrier localization effects was that of [Watson-Parris et al. \(2011\)](#). Their starting point was a one-band effective mass model for electrons and holes. However, instead of treating the QW problem as an ideal one-dimensional problem, a full three-dimensional representation of the QW was considered. Thus, at each grid point in the three-dimensional supercell, used to solve the Schrödinger equation, different material compositions have been considered. In other words, the grid points inside the (In,Ga)N QW region can be either InN or GaN. The number of InN grid points inside the QW region determines then the InN content of the QW system. This method can also account for strain and piezoelectric effects, again using the material parameters corresponding to InN or GaN at each grid point. Thus, insight can be gained into the effect of carrier localization due to variations in the InN content employing a modified continuum-based approximation. However, this method requires full solution of the Schrödinger equation $H\psi = E\psi$ for the random potential, which becomes computationally expensive if included e.g., in a self-consistent solution to carrier transport in a heterostructure.

To address this issue, a very interesting method has recently been proposed and used in the literature. [Filoche et al. \(2017\)](#) have introduced a new approach, the so-called *localization landscape theory*. In this approach, instead of solving the Schrödinger equation, one deals with the problem $Hu = 1$. It can be shown that u is connected to the ground state energy and wave function. For square wells this method is in excellent agreement with the formal solution of the Schrödinger equation. Furthermore, it also turns out that $1/u$ describes an effective potential which, when compared to the results from a full Schrödinger equation of a disordered system, gives a very good indication in which regions the wave functions are localized. Since $W = 1/u$ is related to an effective potential and describes regions in which the carriers are localized, it is called *localization landscape theory*. Overall, the benefit of this method is that instead of solving a large (sparse) eigenvalue problem, one is left with solving a set of linear equations, which is computationally significantly cheaper. Furthermore, the effective potential W is also extremely useful for treating disorder and localization effects in drift-diffusion-based transport calculations ([Li et al., 2017](#); [O'Donovan et al., 2021](#)). Here, W can be included in these calculations to treat composition fluctuations and to mimic effects such as tunneling that are not intrinsically accounted for in standard drift-diffusion simulations. This approach is sometimes called a quantum corrected transport model. More details can be found in Refs. [Li et al. \(2017\)](#) and [O'Donovan et al. \(2021\)](#).

However, in comparison to the modified continuum-based model described above, for instance used by [Watson-Parris et al. \(2011\)](#) to address alloy fluctuations and carrier localization features, it is not obvious how to treat multi-band models within localization landscape theory. This makes the method problematic to apply to extreme alloys such as $\text{GaN}_x\text{As}_{1-x}$, where the BAC model is intrinsically a multi-band approach. By contrast, it is straightforward to include multiple bands in the approach used by [Watson-Parris et al. \(2011\)](#). Additionally, to obtain reliable results from $Hu = 1$, the energy zero must be chosen carefully. Especially when dealing with (In,Ga)N/GaN multi-QW (MQW) systems, where one is left with a triangular shaped conduction and valence band profile, which also varies between the wells due to the built-in potential, attention has to be paid to the aspect of the zero of energy choice. Here, the system may be partitioned in smaller sub-systems and the energy zero of each of these sub-systems is adjusted ([O'Donovan et al., 2022](#)). Additionally, and in contrast to solving Schrödinger's equation, the solution of $Hu = 1$ gives initially only access to ground state energies. However, here also approaches can be chosen to obtain the densities of states within this method ([Piccardo et al., 2017](#)).

Motivated by the interest in the localization landscape approach, and by the challenges associated both with choosing a zero of energy and determining the densities of states, other approaches have recently been proposed to provide robust quantum-corrected models for simulation of disordered systems. Detailed analysis has shown that application of the Hamiltonian H recursively to random wave functions (RWF) or application of a universal low-pass filter (ULF) to the random potential can provide a more accurate quasi-classical description of the temperature-dependent carrier density, $n(r, T)$ in an effective potential ([Gebhard et al., 2023](#); [Nenashev et al., 2023](#)). While both of these approaches look very promising, they have not, at the time of writing, been used yet to analyze a realistic disordered semiconductor structure.

Overall, given that these different approaches are numerically cheap compared to DFT, they can treat disordered QWs of realistic sizes and dimensions and give first insight into carrier localization effects. But they have the drawback that they do not allow for an atomistic, microscopic description of the system. The question here is then, is it justified to assume that one uses the bulk material parameters e.g., for pure InN or GaN at neighboring sites without modifications? This asks also the question what grid size should be chosen so that this becomes a good approximation? From a fundamental point of view, these modified continuum-based approximations cannot provide any insight into the question of how important for instance In—N—In chains are for carrier localization effects in (In,Ga)N or to what extent neighboring N atoms will modify the electronic structure of Ga(N, As).

As discussed above, DFT can give insight into such questions, but due to its computational expense, this can only be done for small supercells. Consequently, DFT might fail to shed light onto connected carrier localization features.

Thus, theoretical models are desirable which provide insight into these questions on an atomistic, microscopic level, while at the same time being able to deal with large supercells, and so treat realistically sized heterostructures. Two methods which meet these criteria are the so-called (*semi*-) *empirical pseudo-potential method* (EPM) and the (*semi*-) *empirical tight-binding model* (ETBM). These approaches can then also provide benchmarks and/or further inputs into e.g., a localization landscape treatment of alloy induced carrier localization effects in semiconductor QWs. The following sub-sections briefly review ETBM and EPM.

Semi-empirical atomistic approaches

Having motivated the need for empirical atomistic electronic structure theories, we now briefly introduce the basic concepts of (empirical) tight-binding and empirical pseudopotential theory. For more details we refer to textbooks (O'Reilly, 2002; Harrison, 2005).

Empirical tight-binding theory

The basic idea underlying the tight-binding (TB) model is that the electronic band structure can be described by starting from the limit of isolated atoms. Thus, localized orbitals at the different atoms in the unit cell or for bigger systems in the supercell form the basis states of the TB approach. The TB model offers a transparent approach since the involved matrix elements are described in the language of overlaps of (localized) atomic-like orbitals. Therefore, this method has a simple physical interpretation.

Two main assumptions are made in every TB model, namely (i) the bulk band structure can be accurately described by a small number of basis states per unit cell and (ii) with increasing distance between atom positions, the overlap of the strongly localized atomic-like orbitals decreases rapidly. Popular TB approaches are the so-called nearest neighbor sp^3 , sp^3s^* or $sp^3d^5s^*$ models (Caro et al., 2013; Vogl et al., 1983; Jancu et al., 2002; Schulz et al., 2015a). For instance, in the case of a nearest neighbor sp^3 TB model one takes one s - and three p -orbitals (p_x, p_y, p_z) per lattice site into account.

One of the main tasks to establish a TB model is the calculation/determination of the overlap matrix elements between different orbitals at different sites. The matrix elements are generally obtained by treating them as fitting parameters. This leads to the so-called *empirical TB model* (ETBM). Here parameters are fitted to characteristic bulk band structure features such as band gaps and effective masses. The ETBM provides a microscopic description of the solid since in the underlying picture, interactions between for example an s -orbital on an In atom with a p_x -orbital on a N atom are accounted for.

So far, we have discussed the ETBM method only for bulk systems. However, a few extra ingredients are required to describe alloys on a microscopic level. We illustrate the general procedure here on the basis of a wurtzite c -plane (In,Ga)N/GaN QW. Also, since most of the ETBMs applied to III-V systems are nearest neighbor models, we will assume a nearest neighbor model in the following. As a first step, it is necessary to have parameters suitable for each of the constituent materials, in this case GaN and InN. Next it is necessary to choose a suitable averaging approach for the self-energy parameters of atoms such as N which can have differing numbers of In and Ga atoms.

Due to the lattice mismatch between InN and GaN, also strain effects need to be accounted for in the model. To do this, it is required to first establish the new equilibrium positions of the different atoms in an atomistic picture of the alloy. This is generally achieved using so called *valence force field* (VFF) models (Keating, 1966; Martin, 1970). In general these models are parameterized in terms of bond-bending and bond-stretching contributions with free adjustable parameters. VFF models with different levels of complexity on the level of interactions accounted for can be found in the literature (Schulz et al., 2015a; Keating, 1966; Martin, 1970; Camacho and Niquet, 2010). Once such a VFF model is developed and established, the new equilibrium positions of the In, N, and Ga atoms in an alloy or heterostructure can be found by minimizing the total elastic energy of the simulation cell. With the relaxed atomic positions being determined, the original bulk TB matrix elements must be adjusted to account for the strain in the system (Caro et al., 2013; Vogl et al., 1983; Jancu et al., 2002; Schulz et al., 2015a).

The last ingredient to a TB model describing the electronic properties of $\text{In}_x\text{Ga}_{1-x}\text{N}$ systems is the (local) built-in potential arising from the spontaneous and strain-induced piezoelectric polarization response discussed already above. To include the built-in potential $\phi(\mathbf{r})$ in the ETBM description, the widely used ansatz is a site-diagonal correction to the Hamiltonian. In general, the built-in potential can be obtained from solving Poisson's equation. However, for an underlying wurtzite lattice plus the fact that the underlying lattice is even further modified by the presence of (local) strain fields, solving Poisson's equation is non-trivial. As example, the bond distances in InN are much larger (by about 10%) when compared to GaN. Thus, in (In,Ga)N large local strains can be present around In, N or Ga atoms. Given that the piezoelectric response is strain dependent, local piezoelectric polarization can play an important role and might affect carrier localization effects significantly on a microscopic level. To take effects arising from local strain and disorder on piezoelectric polarization and thus the local built-in potential into account, a local theory of polarization was developed (Caro et al., 2013). The theory relies on decoupling the macroscopic and local contributions to the total polarization; the latter can be evaluated at each atomic site. The connected (local) built-in potential can be calculated from a point-dipole model. More details of the whole method and an in-depth discussion are given in Ref. Caro et al. (2013).

In summary, within this framework an atomistic description of the electronic structure of III-N alloys and heterostructures of realistic size can now be achieved. This approach accounts for the underlying microscopic alloy structure, such as In—N—In chains. It is a multi-band approach, thus includes band mixing effects and, due to its semi-empirical nature, very large supercells can be studied. A schematic illustration of the typical workflow is given in Fig. 3.

Fig. 3 Schematic visualization of the workflow using empirical tight-binding theory for modeling the electronic structure of wurtzite III-N alloys and heterostructures. A similar workflow can be applied for zincblende alloys, often without the need to include local polarization potential fluctuations.

Another way to achieve an atomistic description of the electronic structure of semiconductor alloys or nanostructures is the *empirical pseudo-potential method (EPM)*. This method requires basically the same ingredients (VFF model, local polarization theory, etc.) as the ETBM. The main difference between the two methods is the electronic structure theory, thus how the underlying Hamiltonian is constructed.

Empirical pseudo-potential method

We review here the basic idea underlying electronic structure calculations within the framework of the EPM. We focus here on bulk systems since transferring this approach to a nanostructure is basically following the same steps as in the ETBM case. For more details on this aspect, we refer to the literature (Bester, 2009).

In general, the EPM approach is similar to the TB ansatz. This means in the EPM the time-independent Schrödinger equation for a bulk system is solved without knowing the exact potential in which the electrons are moving. Here one relies on an effective potential (Harrison, 2005; Cohen and Chelikowski, 1989). The EPM also starts from the idea that core electrons are tightly bound to the nuclei. Furthermore, the assumption is that they contribute only very little to conduction and valence band states and thus to the electronic properties near the band edges. Additionally, the assumption is made that the core electrons are unaffected by the change in environment of a solid (frozen core approximation). Within this frame the basic task is to find a scheme that removes the core electron contributions from the total wave function. Compared to the behavior of the wave function outside the core, the wave function changes rapidly (oscillates) inside the core region. A large number of plane waves would be required to describe this behavior, making such a calculation numerically heavy. However, as already discussed above, the behavior of the wave function in the core region is of secondary importance for the states around the conduction and valence band edge. The basic idea now is to find a pseudo-potential that results in a slowly varying wave function in the core region but reproduces at the same time the 'original' wave function outside the core region. Therefore, one is left with the problem of determining such a pseudo-potential.

To address now a nanostructure based on for instance (In,Ga)N, similar to the ETBM, the empirical pseudo-potentials are constructed from independent binaries (e.g., InN and GaN). Thus, one faces here also the problem of describing the pseudo-potentials of the common anion species (i.e., N) in (In,Ga)N since the empirical pseudo-potentials for N in InN and GaN are most likely to be different. In general, here also weighted averaging procedures for the empirical pseudo-potentials are employed (Bester, 2009). Once the empirical pseudo-potentials are derived, a similar work flow applies as in the ETBM approach (cf. Fig. 3), meaning that the equilibrium atomic positions and the connected built-in potentials are required, which form then input for solving Schrödinger's equation in the frame of the EPM. A detailed overview of the method can be found in Ref. Bester (2009), for instance.

Having discussed different theoretical methods to address carrier localization effects in III-V bulk alloys and heterostructures, we now turn to present some of the theoretical conclusions that have been drawn on the basis of these approaches.

Overview of carrier localization effects in (In,Ga)N, (Al,In)N and (Al,Ga)N systems: Similarities and differences

Equipped with knowledge of the basic concepts and ingredients of the different theoretical models to describe the electronic and optical properties of semiconductor systems, we give a brief overview of carrier localization effects in the III-N alloys (In,Ga)N, (Al,In)N and (Al,Ga)N. It is well established that localization effects play a key role in each of these three systems. Comparing the similarities and differences between the three alloys allows us to draw useful overall conclusions. We will focus on both bulk systems and heterostructures, here in particular on QWs.

Overall, it should be noted that, despite its importance, the impact of carrier localization and its consequences for electronic and optical properties of III-N structures has been widely neglected in the theoretical analysis of these systems and only recently a strong focus has been placed on this aspect. On the one hand this is surprising. Experimental studies gave clear indications that carrier localization effects can dominate the fundamental properties of, for instance, (In,Ga)N/GaN QW systems. However, as we have seen

above, the theoretical description of these systems requires a far more complex modeling procedure when compared to other III-V alloys such as (In,Ga)As/GaAs systems. We start the overview here with (In,Ga)N/GaN systems. In a second step, we turn our attention to (Al,In)N before finally discussing (Al,Ga)N-based structures.

(In,Ga)N alloys and heterostructures

Different experimental features gave clear indications of carrier localization effects in (In,Ga)N systems. For instance, blue emitting (In,Ga)N-based devices exhibit high quantum efficiencies, even though they display extremely high defect densities (Dawson et al., 2016). The widely accepted explanation for the defect insensitivity is that the carriers are spatially localized due to alloy fluctuations, preventing them from diffusing to defects (Nakamura and Chichibu, 2000; Humphreys, 2008).

Probably one of the first theoretical studies on carrier localization in (In,Ga)N alloys was performed by Bellaiche et al. (1999) using the EPM. These calculations on large, bulk zincblende supercells, assuming a random distribution of In atoms in the alloy, revealed hole localization near In atoms. Wang (2001) performed an analysis similar to Bellaiche et al. (1999) but this time for a wurtzite system, which also revealed hole localization around In—N—In chains in the alloy. Calculations based on DFT within the LDA framework further supported the EPM results (Schulz et al., 2015b). Overall, these empirical atomistic and also DFT-based calculations revealed a strong asymmetry in the localization behavior of electrons and holes in (In,Ga)N bulk systems.

All the above discussed calculations and conclusions were based on bulk systems. However, in a wurtzite (In,Ga)N/GaN QW system several new factors contribute. For instance, given that the (In,Ga)N QW is grown on GaN, the QW is strained to the GaN barrier. Furthermore, due to the interfaces between (In,Ga)N and GaN in (In,Ga)N/GaN QWs grown along the polar c -axis, strong electrostatic built-in fields are present, which lead to a spatial separation of the carriers along the growth direction (c -axis), as already discussed above. This macroscopic built-in field is not present when dealing with bulk systems. Additionally, the combination of built-in field and (In,Ga)N—GaN interfaces also gives rise to the question how interface roughness, e.g., well width fluctuations, affects electronic and optical properties of these heterostructures. Again, this factor does not contribute in the bulk situation.

The first theoretical work to shed light on the question of carrier localization in realistically sized wurtzite c -plane (In,Ga)N/GaN QWs was performed by Watson-Parris et al. (2011) using the modified single-band effective mass approximation discussed above. Their calculations showed that random alloy effects are sufficient to localize holes. Additionally, when including well width fluctuations in the form of disk-like structures at the interface between the (In,Ga)N well and the GaN barrier, as indicated in experiment (Watson-Parris et al., 2011), they also found that these structural inhomogeneities can localize electron wave functions. Thus, both types of carriers (electrons and holes) are localized in c -plane (In,Ga)N/GaN QWs at opposite interfaces due to the presence of the built-in field. This result was later also confirmed by Schulz et al. (2015a) in the framework of atomistic ETBM calculations. Fig. 4 shows results of such a calculation. The effect of the Coulomb interaction between the carriers may modify the

Fig. 4 Calculated isosurfaces of the electron (red) and hole (green) ground state charge densities in a c -plane $\text{In}_{0.15}\text{Ga}_{0.85}\text{N}/\text{GaN}$ quantum well. The results are shown in the absence (“Without Coulomb”; left) and in the presence of Coulomb effects (“With Coulomb”; right). The isosurfaces are depicted at 10% and 50% of the respective maximum charge densities. The quantum well interfaces are indicated by the dashed lines. The “Topview” shows a view parallel to the c -axis while “Sideview” is a view perpendicular to the c -axis. The in-plane dimensions of the cell are $10\text{ nm} \times 9\text{ nm}$ and along the c -axis the cell dimension is 10 nm . The quantum well width is approximately 3.4 nm . A well width fluctuation with a diameter of 5 nm and height of 2 monolayers has been included in the calculations. A random distribution of In atoms has been assumed here.

picture of independently localized carriers. Schulz et al. (2015a) thus extended the atomistic ETBM analysis and accounted for Coulomb effects (excitonic effects) and their analysis revealed that the combination of carrier localization due to (i) built-in fields, (ii) alloy fluctuations and (iii) structural inhomogeneities (well width fluctuations) dominate over the attractive Coulomb interaction between the carriers, at least for the systems studied. Further studies (Tanner et al., 2018; David and Weisbuch, 2022) also focused on the impact of the well width and how the picture is changed when well width fluctuations are absent. For narrower wells the interplay of well width, carrier localization and Coulomb effects is more involved and less clear cut. Nevertheless, carrier localization effects play a dominant role so that the wave function overlap is still strongly dependent on the alloy microstructure.

In addition to *c*-plane (In,Ga)N/GaN QWs, (In,Ga)N/GaN QWs grown on so-called *non-* or *semipolar planes* have attracted considerable interest (Schwarz and Kneissl, 2007; Waltereit et al., 2000). This originates from the fact that these structures ideally promise reduced (semipolar) or even the complete absence (nonpolar) of macroscopic electrostatic built-in fields. Clear experimental evidence has been given that alloy disorder induced carrier localization effects also play a significant role for understanding the electronic and optical properties of such heterostructures (Sutherland et al., 2015; Mounir et al., 2016).

The first theoretical, atomistic analysis of these systems, in conjunction with atom probe tomography (APT) and time resolved PL measurements, revealed that, when neglecting Coulomb effects, the hole wave function is localized by the random alloy fluctuations while the electron charge density is less affected by the local effects and to a first approximation spreads out over the entire QW region. An example of this situation is given in Fig. 5 (left) for the electron and hole ground state charge densities in a *m*-plane $\text{In}_{0.17}\text{Ga}_{0.83}\text{N}/\text{GaN}$ QW. However, when combining the ETBM with configuration interaction calculations to account for the attractive electron hole Coulomb interaction, the theoretical studies revealed that the electron localizes about the hole, which is still localized by the random alloy fluctuations. An example of the situation is given in Fig. 5 (right). Thus, the theoretical analysis predicted exciton localization effects in *m*-plane (In,Ga)N/GaN QWs, consistent with the experimentally observed single-exponential PL decay curves (Marcinkevičius et al., 2013; Sutherland et al., 2015; Schulz et al., 2015c). Thus the situation in a non-polar *m*-plane system is very different from a *c*-plane system where one is basically left with independently localized carriers (or strongly varying wave function overlaps in narrower wells).

In summary, it can be seen that electron wave functions are far less affected by random alloy fluctuations, at least when compared to holes in (In,Ga)N bulk and (In,Ga)N/GaN QW systems. For holes already the presence of an In—N—In chain is sufficient to introduce strong localization effects. Even though these localization effects are very strong in (In,Ga)N systems and can dominate their optical properties, we will see in the next sub-section that localization features can be even more dramatic in (Al,In)N, reflecting the greater difference in size and electronegativity between In and Al compared to In and Ga.

(Al,In)N systems

The III-N alloy (Al,In)N has attracted significant research interest given its potential for electronic and optoelectronic devices such as high-electron-mobility transistors, high-frequency and high-power microwave devices (Pandey et al., 2012), and for devices operating in the deep UV spectral region (Tan et al., 2016). This interest originates from the fact that AlN has a band gap (6.0–6.25 eV) that is even larger than the band gap of GaN (3.5 eV) (Moses et al., 2011; Vurgaftman and Meyer, 2003). Thus, by replacing Al by In in AlN, emission in the UV spectral region can, in principle, be tailored to specific applications. However, compared to (Al,In)N, (In,Ga)N looks like a well characterized system in terms of its fundamental properties. For instance, the band

Fig. 5 Isosurfaces of the electron (red) and hole (green) ground state charge densities in a *m*-plane $\text{In}_{0.17}\text{Ga}_{0.83}\text{N}/\text{GaN}$ quantum well. The isosurfaces are plotted at 10% and 25% of the respective maximum charge density values. The quantum well width is 2 nm and a disk-like well width fluctuation with a diameter of 5 nm and height of 2 monolayers has been considered here. The quantum well interfaces are schematically indicated by the dashed lines. The overall cell dimensions are 10 nm × 9 nm × 10 nm. The “Top View” displays a view along the *m*-axis, while “Side View” corresponds to a view perpendicular to the *m*-axis. Data in the absence of Coulomb effects are shown in the left panel (“Without Coulomb”); in the presence of Coulomb effects the results are depicted in the right panel of the figure (“With Coulomb”). More information about the calculations can be found in Ref. (Schulz et al., 2015c).

gap variation of (Al,In)N alloys with In content is key when designing optoelectronic devices operating in the UV spectral region utilizing these alloys. For most other III-V materials, it is found that the band gap of an alloy $A_{1-x}B_xC$ varies approximately linearly with composition x . Cations of the alloy in question are denoted by A and B while C denotes the anion. Any deviation from this linear behavior is usually accounted for by a small quadratic term, $-b \cdot x \cdot (1 - x)$ (Vurgaftman et al., 2001). The quantity b is the so-called *band gap bowing parameter*. This approximation is sometimes called the *virtual crystal approximation* (VCA) since the material parameters can be smoothly interpolated between the binary materials AC and BC. However, the alloy microstructure change is not taken into account. Both experimentally and theoretically clear indications are given that (Al,In)N is not a “standard III-V alloy” and that VCA breaks down. For instance, Sakalauskas et al. (2010) extracted, based on their experimental data over the full composition range, a *composition dependent* bowing parameter $b(x)$, with values of $b(x)$ as large as 6.4 eV for the A-valence band transition at small In composition x , e.g., 5% In. Similarly, DFT calculations based on small supercells revealed a *composition dependent* bowing parameter (Pela et al., 2011). While both results pointed in the direction of a composition dependent bowing parameter, the fundamental physics origin of this behavior was unclear.

To understand further the fundamental properties of (Al,In)N alloys, Schulz and co-workers performed large scale DFT based calculations for this system (Schulz et al., 2014). Their analysis revealed that a single, isolated In atom results in a strongly localized state above the conduction band edge (CBE). They found also that this localized state hybridizes with and modifies the CBE state. In other words, the CBE state in (Al,In)N is a linear combination of the AlN CBE state and the localized state (CBE+1) introduced by the single In atom. Thus, these studies gave clear evidence of a cation-based (In-based) *band-anticrossing* (BAC) and localization in the conduction band of (Al,In)N alloys. Furthermore, Schulz et al. extended the DFT based analysis to higher In contents. Here special attention was again paid to the impact of In—N—In chains on the electronic structure (Schulz et al., 2014). From the review above of carrier localization in (In,Ga)N alloys, one knows already that In—N—In chains can effectively localize hole wave functions: a similar effect was found by Schulz et al. in (Al,In)N (Schulz et al., 2014).

Overall, carrier localization effects in (Al,In)N alloys are therefore even more pronounced when compared to (In,Ga)N systems. This originates from the strong difference in size and electronegativity of In and Al atoms, so that even a single In atom in an AlN host matrix leads to a localized state in the conduction band. Perhaps uniquely for a III-V semiconductor, localization effects are found in both the conduction and valence band, leading to a strong reduction in band gap energy of the alloy and consequently to a composition dependent bowing parameter, consistent with several experimental studies (Sakalauskas et al., 2010; Schulz et al., 2013). Since (Al,In)N systems are potential candidates for light sources in the UV spectral region, a detailed understanding of the band gap energy variation with composition and of carrier localization effects are key for designing such emitters. Additionally, theoretical studies not only revealed that the band gap variation but also light polarization characteristics of (Al,In)N alloys are significantly affected by carrier localization effects (Schulz et al., 2013), again an important aspect especially for designing light emitters operating in the deep UV spectral region.

(Al,Ga)N systems

As a final example, we consider wurtzite $Al_{1-x}Ga_xN$ alloys, which are also of major interest for light emitters operating in the UV spectral range (Humphreys, 2008). Because Al and Ga are more similar to each other than either is to In, carrier localization effects are more subtle but still remain important in (Al,Ga)N bulk alloys and heterostructures, and so the impact of these effects should also be included for describing their electronic and optical properties accurately.

Overall, experimental and theoretical data on (Al,Ga)N *bulk* systems indicate that in comparison to (In,Ga)N or (Al,In)N systems, carrier localization effects are less pronounced but still present. In heterostructures, the electrostatic built-in fields and possible QW widths or (barrier) alloy fluctuations can come into play. Thus, even though the active region in a GaN/(Al,Ga)N QW or QD system is pure GaN, the barrier material is (Al,Ga)N. Furthermore, given that the built-in potential in *c*-plane structures forces the wave functions of electrons and holes to the GaN/(Al,Ga)N interfaces, alloy fluctuations may become important. While experimental data give indications of carrier localization in (Al,Ga)N QW systems (Leroux et al., 1998; Sabooni et al., 2007; Frankerl et al., 2020), theoretical studies have only recently been employed that take potential carrier localization effects in these systems into account. Calculations in the framework of modified continuum-models (**k**·**p**) targeted the question of the importance of alloy fluctuations in the barrier material for the optical properties of GaN/(Al,Ga)N QWs (Rigutti et al., 2016; Roble et al., 2019). These studies revealed that the combined effect of built-in field and alloy fluctuations lead to hole localization and a much weaker electron localization; when accounting for excitonic effects the hole wave function is still localized by alloy fluctuations, while the electron tends to localize about the hole wave function due to the attractive Coulomb interaction (Roble et al., 2019). Studies on the impact of alloy disorder in (Al,Ga)N QWs with AlN barriers (Finn et al., 2022) further supported the observation of hole localization effects in (Al,Ga)N heterostructures; this finding was independent of the Al content in the well. These atomistic studies indicated also that at higher Al (>50%) contents electron localization may become relevant as the effective electron masses of AlN and GaN are significantly higher when compared to InN.

All these considerations and results highlight that carrier localization can also play a role in (Al,Ga)N heterostructures. On the theoretical side and compared to (In,Ga)N or even (Al,In)N systems, far less attention has been directed towards these effects in (Al,Ga)N structures. However, given the importance of (deep) UV light emitters for a wide range of applications, and building on the model development already carried out for instance for (In,Ga)N systems, studies of the impact of alloy disorder and carrier localization effects on the properties of (Al,Ga)N heterostructures has recently gained strong momentum and continues to grow.

Conclusion

In this chapter an overview of different theoretical methods to study the electronic structure of disordered alloys and heterostructures has been presented. These methods were discussed with respect to their capability of treating alloy fluctuations and potentially connected carrier localization effects. The starting point here was density functional theory (DFT). While this method provides insight into carrier localization features due to alloy fluctuations on a microscopic level, it is in its standard implementation only applicable to small supercells. This presents especially a problem when looking at heterostructures such as quantum wells (QWs), where not only the active region of the system (QW) but also the barrier material must be treated explicitly. Empirical atomistic models, e.g., empirical tight-binding or empirical pseudopotential methods, allow for a description that treats explicitly hundreds of thousands of atoms. However, in these empirical atomistic methods the parameter extraction is more complicated, and the cost of calculations in general remains too high to treat device simulations self-consistently.

This issue can be circumvented by using continuum-based approximations, e.g., multi-band $\mathbf{k}\cdot\mathbf{p}$ models. The impact of localized states in extreme alloys such as $\text{GaAs}_{1-x}\text{N}_x$ can also be treated by adding additional bands associated with the localized states to the conventional $\mathbf{k}\cdot\mathbf{p}$ Hamiltonian, in what is referred to as a band-anticrossing (BAC) model. However, the drawback here is that both conventional and BAC $\mathbf{k}\cdot\mathbf{p}$ models, in general, treat the system as a continuum which is described by average material parameters. To address this issue, modified continuum-based approaches have been established where at different grid points of the simulation cell different alloy compositions are considered. While this gives then a three-dimensional description of the system and the alloy fluctuations, it still remains computationally expensive for device simulations.

To avoid full solution of the Schrödinger equation $H\psi = E\psi$ for a random potential, a very interesting approach has recently been proposed and used in the literature, the so-called *localization landscape theory*. In this approach, instead of solving the Schrödinger equation, one deals with a one-band problem $Hu = 1$. It can be shown that $1/u$ describes an effective potential, W , which, when compared to the results from a full Schrödinger equation, gives a very good indication in which regions the wave functions are localized. Furthermore, the effective potential W is then extremely useful for treating disorder and localization effects in self-consistent drift-diffusion-based transport calculations, giving what is sometimes called a quantum corrected transport model.

The localization landscape approach has challenges associated e.g., with choosing a zero of energy and determining the densities of states. Other approaches have therefore recently been proposed to provide robust quantum-corrected models. Detailed analysis has shown that application of the Hamiltonian H recursively to random wave functions (RWF) or application of a universal low-pass filter (ULF) to the random potential can provide a more accurate quasi-classical description of the temperature-dependent carrier density, $n(r, T)$ in an effective potential. While both of these approaches look promising, they have, at the time of writing, still to be applied to analyze a realistic disordered semiconductor structure.

Overall, given that these different continuum approaches are numerically cheap compared to the atomistic DFT and empirical tight-binding and pseudopotential approaches, they can treat disordered QWs of realistic sizes and dimensions and give valuable insight into carrier localization effects. But they have the drawback that they do not allow for an atomistic, microscopic description of the system. The question here is then, is it justified to assume that one uses the bulk material parameters e.g., for pure InN or GaN at neighboring sites without modifications? This asks also the question what grid size should be chosen so that this becomes a good approximation? From a fundamental point of view, these modified continuum-based approximations cannot provide any insight into the question of how important for instance In—N—In chains are for carrier localization effects in (In,Ga)N or to what extent neighboring N atoms will modify the electronic structure of Ga(N,As).

Thus, theoretical models which provide insight into these questions on an atomistic, microscopic level, while at the same time being able to deal with large supercells remain essential. The *(semi-) empirical pseudo-potential method (EPM)* and the *(semi-)empirical tight-binding model (ETBM)* both meet these criteria. These approaches are often benchmarked against DFT calculations but can then serve to provide benchmarks and or further inputs into e.g., a localization landscape treatment of alloy induced carrier localization effects in semiconductor QWs. Overall, we conclude that calculations across different length scales remain essential for a reliable description of localization effects in disordered semiconductors and thus their electronic, optical and transport properties.

Having reviewed the advantages and disadvantages of the different methods, we overviewed their application by taking III-N alloys as exemplar materials and addressing the similarities and differences between carrier localization features in (In,Ga)N, (Al,In)N and (Al,Ga)N systems. Starting with (In,Ga)N systems, calculations on both bulk alloys and QWs revealed strong hole localization effects. Here already random alloy fluctuations and the introduction of In—N—In chains are sufficient to lead to hole localization features. For electrons the situation is different. In bulk systems, and in comparison to hole states, random alloy fluctuations have a much weaker effect on electron wave functions. Similar effects are seen in *non-polar* (In,Ga)N/GaN QW systems when assuming a random distribution of In atoms in the active region. However, in a *polar c-plane* QW system, due to the presence of the strong electrostatic built-in field, well width fluctuations can act as localization centers for electron wave functions.

Turning to (Al,In)N systems, localization effects are even more pronounced when compared to (In,Ga)N alloys, reflecting the larger difference between AlN and InN than between GaN and InN. Here, already a single In atom in a large AlN host matrix gives rise to electron localization effects in the conduction band, with their impact on the conduction band edge being well described using a BAC model. In addition to this, when two In atoms share a N atom, strong hole localization effects are observed, similar to (In,Ga)N. These localized states in the conduction and valence band of (Al,In)N alloys are manifested by a composition dependent band gap bowing parameter.

Studies on (Al,Ga)N *bulk* systems indicate that carrier localization features are less pronounced, at least compared to (In,Ga)N or (Al,In)N alloys, in line with the fact that Al and Ga are more similar to each other than either is to In. Despite this, some localization effects can be observed in *c*-plane GaN/(Al,Ga)N QW and QD structures. Although the active region is mainly pure GaN, at the QW-barrier interface alloy fluctuations become important due to the presence of the electrostatic built-in field in these systems and the connected spatial separation of electron and hole wave functions. Here, calculations again reveal hole localization effects while the electron wave functions are only slightly perturbed by the presence of the random alloy fluctuations at least when compared to the hole. Similar observations have been made in (Al,Ga)N QWs with pure AlN barriers.

Overall, even though significant progress has been made in the theoretical description and understanding of electronic and optical properties of semiconductor alloys and heterostructures over the last few years, there still remain several open questions and challenges related to the impact of disorder. For instance, the question of how radiative recombination rates in III-N QWs are affected by random alloy fluctuations in comparison to virtual crystal type calculations is still under discussion. Additional questions are related to *non-radiative recombination processes* such as *Auger recombination*. In (In,Ga)N/GaN QW systems the widely used approximation to determine Auger coefficients builds on continuum-based models neglecting carrier localization effects. This means that these studies apply *k*-selection rules for transitions between different states. However, due to the presence of intrinsic alloy fluctuations and associated carrier localization effects, these symmetries/selection rules are no longer applicable given that the translational symmetry of the system is broken. A first work by Jones et al. (2017), using a modified single-band continuum approach, started to look at this problem. These calculations revealed that for (In,Ga)N/GaN QWs, Auger coefficients involving two holes and one electron (hole-hole-electron) are larger in magnitude than the coefficient related to processes involving two electrons and one hole (electron-electron-hole). A similar conclusion was derived in a recent atomistic investigation (McMahon et al., 2022) of Auger effects that accounted for alloy disorder and temperature effects, but performed calculations at fixed carrier density, thus focusing on the thermal rather than the current “droop”. Experimental and theoretical studies (Jones et al., 2017; McMahon et al., 2022; Nirschl et al., 2016) of Auger recombination give non-conclusive answers to which of the different processes (electron-electron-hole or hole-hole-electron) dominate, and may contradict each other. All this indicates that further studies are still required to fully understand the impact of carrier localization effects on the electronic and optical properties of semiconductor alloys and connected heterostructures, in order to ultimately exploit their full potential for future novel and energy efficient device applications.

Abstract

One important way to characterize a material is in terms of its electrical conductivity (or the inverse, its electrical resistivity). A metal conducts electricity well, and its resistivity usually increases with increasing temperature. Most elements (82 of the 104 naturally occurring ones) are metals. A semiconductor conducts electricity less well, and its resistivity usually decreases with increasing temperature. An insulator hardly conducts electricity at all; its resistivity is very large. This article deals with the electrical resistivity of pure metals and alloys. The focus is mainly on nonmagnetic metals—magnetic metals are covered elsewhere. References to both the theory of the electrical resistivity of metals, and to data on the resistivities of pure metals and alloys, are given in the Further reading section.

Introduction

Formally, the electrical conductivity tensor σ (and its inverse—the resistivity tensor ρ) are defined by Ohm's law:

$$\mathbf{J} = \sigma \cdot \mathbf{E} \quad (1)$$

and

$$\mathbf{E} = \boldsymbol{\rho} \cdot \mathbf{J} \quad (2)$$

where $\mathbf{J}$ is the current density and $\mathbf{E}$ is the electric field (both vectors). In the general case, $\boldsymbol{\rho}$ is the inverse of the tensor σ . However, if no magnetic field is present, and if the crystal structure of the metal is cubic—simple cubic (s.c.), face-centered cubic (f.c.c.), or body-centered cubic (b.c.c.)—then σ and $\boldsymbol{\rho}$ reduce to scalars, and $\rho = 1/\sigma$. Since many of the most common metals have cubic structures, the focus is on the case where ρ and σ are scalars, in which case it suffices to consider ρ , because σ is simply its inverse. Where appropriate, noncubic metals are discussed.

Near room temperature (~ 295 K), convenient units for ρ are micro-ohm cm ($\mu\Omega$ cm), since the resistivities of all pure elemental metals at 295 K range from $\sim 1.6 \mu\Omega$ cm for Ag to somewhat over $100 \mu\Omega$ cm for Mn, Gd, and Tb.

Measurements

The resistivity ρ at temperature T , $\rho(T)$, of a given metal or alloy is derived from a “four-probe” measurement of the electrical resistance $R = V/I$ of a long thin wire of known cross-sectional area $A = \pi r^2$, or a long, narrow film of area $A = Wt$, as shown schematically in Fig. 1. Here r is the radius of the wire, W and t are the width and thickness of the film, and the voltage leads are made long and thin to minimize perturbing the current flow. These geometries minimize end effects, thereby ensuring that the current density $\mathbf{J} = I/A$ is uniform across A , and contact effects by eliminating current flow into the voltage contacts. In such a case, measuring the voltage V across a well-defined length L of the sample gives $\rho = RA/L = VA/IL$.

[☆]Change History: October 2022. J Bass updated the chapter.

Fig. 1 Schematic drawings of (a) Wire and (b) film geometries for measuring resistivities so that complications due to nonuniform current flow and contact resistances are minimal.

Strictly, as noted above, a unique value of $\rho(T)$ can be determined for either a single crystal or a polycrystal line sample of a cubic metal, but only for a single crystal of a noncubic metal that is oriented along a symmetry axis. Even in these cases, it will be seen below that $\rho(T)$ can depend upon the size of the sample if r or t are very small, and upon the content of impurities or other defects such as grain boundaries or dislocation.

Theoretical background

The first derivation of Ohm's law and σ was made by Drude in 1900, who used the classical kinetic theory to treat an assumed gas of free electrons in a metal. His result can be obtained by assuming that an electron of charge e and mass m is accelerated by an electric field E and is subject to a frictional retarding force proportional to its velocity v and inversely proportional to a relaxation time τ (a measure of the average time between scattering events). Then, at steady state, the electron is not accelerated, and

$$m \, dv/dt = 0 = eE - mv/\tau \rightarrow v = eE\tau/m \quad (3)$$

Taking

$$J = nev \quad (4)$$

(where e is the electron's charge and n is the number of electrons per unit volume), Ohm's law is obtained:

$$J = nev = (ne^2\tau/m)E \quad (5)$$

with

$$\sigma = ne^2\tau/m \quad (6)$$

The Bohr-Sommerfeld analysis of a quantum free-electron gas gives a similar expression, but with τ evaluated at the Fermi energy. If a mean free path λ between scattering events is defined as $\lambda = v\tau$, Eq. (6) can be rewritten as

$$\sigma = ne^2\lambda/mv_F \quad (7)$$

Inverting Eq. (7) then gives

$$\rho\lambda = mv_F/ne^2 \quad (8)$$

For a given metal or alloy at temperature T , Eq. (7) shows that $\sigma \propto \lambda$, and Eq. (8) shows that the product $\rho\lambda$ is a constant for a given metal, depending upon the particular metal only through n and v_F . Eq. (8) can be used to estimate λ for a given value of ρ .

To generalize Eqs. (7) and (8) to real (as opposed to free-electron) metals, with real Fermi surfaces, one must turn to a more general analysis, such as the Boltzmann transport equation. Here, one defines an electron distribution function $f(\mathbf{k}, \mathbf{r}, t)$ such that $(4\pi^3)^{-1} \int f(\mathbf{k}, \mathbf{r}, t) \, d\mathbf{k} \, d\mathbf{r}$ gives the number of electrons of wave vector $\mathbf{k}$ (or crystal momentum $\hbar\mathbf{k}$, where $\hbar$ is Planck's constant divided by 2π) at point $\mathbf{r}$ within an element $d\mathbf{r}$ in real space and $d\mathbf{k}$ in wave vector space at time t . $f(\mathbf{k}, \mathbf{r}, t) = 1$ if all states with $\mathbf{k}$ and $\mathbf{r}$ are filled and 0 if all such states are empty. If the electron gas is at thermal equilibrium at a temperature T ,

$$f_0 = 1 / \left(e^{(e - e_F)/k_B T} + 1 \right) \quad (9)$$

is the usual Fermi-Dirac distribution function. The Boltzmann transport equation for $f(\mathbf{k}, \mathbf{r}, t)$ is then

$$\begin{aligned} & \partial f / \partial t + (\partial f / \partial \mathbf{r})(\partial \mathbf{r} / \partial t) + (\partial f / \partial \mathbf{k})(\partial \mathbf{k} / \partial t) \\ & = (\partial f / \partial t)_{\text{scatt}} \end{aligned} \quad (10a)$$

where $(\partial f / \partial t)_{\text{scatt}}$ is the rate of change of f due to scattering from defects, quantized lattice vibrations (phonons), or the sample surface. Since $(\partial \mathbf{r} / \partial t) = \mathbf{v}$, and $\hbar(\partial \mathbf{k} / \partial t) = \mathbf{F}$, any external force $\mathbf{F}$, Eq. (10a) may be rewritten as

$$\begin{aligned} & \partial f / \partial t + \mathbf{v}(\mathbf{k})(\partial f / \partial \mathbf{r}) + (1/\hbar)\mathbf{F}(\partial f / \partial \mathbf{k}) \\ & = (\partial f / \partial t)_{\text{scatt}} \end{aligned} \quad (10b)$$

If both an electric field $\mathbf{E}$ and a magnetic field $\mathbf{B}$ are present, $\mathbf{F} = e\mathbf{E} + \mathbf{v} \times \mathbf{B}$. In the absence of a magnetic field, Eq. (10b) can be rewritten as

$$\begin{aligned} & \partial f / \partial t + \mathbf{v}(\mathbf{k})(\partial f / \partial \mathbf{r}) + (e/\hbar)\mathbf{E}(\partial f / \partial \mathbf{k}) \\ & = (\partial f / \partial t)_{\text{scatt}} \end{aligned} \quad (10c)$$

If the focus is only upon the electrical conductivity σ of the bulk material, the temperature can be taken as constant across the sample, any changes in f with $\mathbf{r}$ can be neglected, and only the steady-state solution can be considered. Eq. (10c) then reduces to

$$(e/\hbar)\mathbf{E}(\partial f / \partial \mathbf{k}) = (\partial f / \partial t)_{\text{scatt}} \quad (10d)$$

Because changes in f with $\mathbf{r}$ are neglected, this equation will not allow one to treat scattering at the sample surface (size effects). Such effects are discussed briefly below.

Finally, for the physics of present interest, the deviations of $f(\mathbf{k})$ from $f_0(\mathbf{k})$ will be small. These deviations can be considered by writing $f(\mathbf{k}) = f_0(\mathbf{k}) + g(\mathbf{k})$. In order to obtain Ohm's law, Eq. (10d) must then be linearized (i.e., drop terms of higher order in $\mathbf{E}$), giving

$$(e/\hbar)\mathbf{E}(\partial f_0 / \partial \mathbf{k}) = (\partial f / \partial t)_{\text{scatt}} \quad (11)$$

Eq. (11) is the linearized Boltzmann transport equation in the absence of temperature gradients, magnetic fields, and size effects. In introductory and intermediate texts, it is usually simplified one more time by making the "relaxation time approximation," that is by taking

$$(\partial f / \partial t)_{\text{scatt}} = -g_k / \tau_k \quad (12)$$

where τ_k is called the relaxation time. Since f_0 (see Eq. (9)) is only a function of the energy ε_k , and $\mathbf{v} = (1/\hbar)\partial \varepsilon_k / \partial \mathbf{k}$, Eq. (11) can be rewritten in the final form

$$e\mathbf{v}_k(\partial f_0 / \partial \varepsilon_k) = -g_k / \tau_k \quad (13)$$

Generalizing Eq. (4) gives $J = \int d\mathbf{k}^3 e g_k \mathbf{v}_k$ and some manipulation of Eq. (13) leads to the relation

$$\sigma = (1/12\pi)(e^2/\hbar) \int \lambda_k dS_k \quad (14)$$

where λ_k is the mean free path of electrons of wave vector $\mathbf{k}$, and dS_k is a differential area on the Fermi surface around wave vector $\mathbf{k}$. Eq. (14) is the generalization of Eq. (7).

For the present purposes, only one more result (the Bloch-Gruneisen equation for the temperature-dependent electrical resistivity of a free-electron gas (i.e., a spherical Fermi surface), in which the electrons are scattered only by phonons and with no participation of reciprocal lattice vectors (i.e., no Umklapp scattering)) is needed. The result, taken as their approximation for the resistivity of an ideally pure metal, ρ_P , is

$$\rho_P = (K/\vartheta)(T/\vartheta)(T/\vartheta)^4 \int_0^{3/T} 4z^4 dz / (e^z - 1) \quad (15)$$

Since the interest here is only in the Bloch-Gruneisen prediction for the temperature dependence of ρ_P , several constants and parameters have been collected together into K , and only scaling parameter, ϑ , is left with the units of temperature.

At high temperatures, where $T \gg \vartheta$, the term $e^z - 1$ in the denominator of the integral reduces to just z , leaving four powers of z inside the integral. The lower limit of the integral then gives zero, and the upper limit is proportional to $(\vartheta/T)^4$, which cancels the $(T/\vartheta)^4$ outside the integral, leaving just (T/ϑ) . In this limit, ρ_P is proportional to T .

At low temperatures, where $T \ll \vartheta$, the upper limit can be approximated as infinity, turning the integral into just a number. The temperature dependence in this limit is then just that outside the integral, or T^5 .

The Bloch-Gruneisen calculation thus predicts that ρ_P should be proportional to T at high T , and to T^5 at low T . A linear variation with T is often seen at high T (but not necessarily extrapolating to $\rho_P = 0$ at $T = 0$ as would be predicted by Bloch-Gruneisen). A strict T^5 variation is rarely, if ever, seen at low T . Deviations from the simple prediction occur for a variety of reasons, including: real Fermi surface effects such as Umklapp scattering; electron-electron scattering (which can give a T^2 variation); deviations from Matthiessen's rule; and the onset of superconductivity.

Experimental temperature and impurity-concentration dependence

From Bloch's theorem, the resistivity of a perfectly periodic metal should be zero. Resistivity results from scattering of conduction electrons by deviations from perfect periodicity, either due to the presence of defects at atomic sites (e.g., impurities, vacancies, dislocations, grain boundaries) or due to vibrations of the atoms of the lattice away from their equilibrium sites (quantized lattice vibrations are called phonons).

In a high-purity metal, scattering by phonons dominates at all but the lowest temperatures. As noted above, for a free-electron metal, the Bloch-Gruneisen model of $\rho(T)$ predicts a linear dependence upon T at high temperatures, and a more rapid decrease at lower temperatures, eventually reaching T^5 at cryogenic temperatures. Figs. 2–4 illustrate some of the behaviors of $\rho(T)$ at higher temperatures, using data for the simple f.c.c. metal Cu, which looks qualitatively like the expectation from Bloch-Gruneisen, the f.c.c. metal Ni, which undergoes a ferromagnetic phase transition at 630 K, and the hexagonal close-packed (h.c.p.) metal Gd, which undergoes magnetic phase transitions at 240 and 293 K. In the simplest case, Cu, at temperatures above ~ 100 K, $\rho(T)$ is approximately linear in T . At cryogenic temperatures, $\rho(T)$ decreases more rapidly than linearly with T . If the metal was perfectly pure, $\rho(T)$ would approach 0 as $T \rightarrow 0$ K, either smoothly if the metal remains "normal" (i.e., nonsuperconducting), or abruptly at a characteristic temperature, T_c , if the metal becomes superconducting. Fig. 5 shows an example of a superconductor, Pb, both in the zero magnetic field (open circles) where it becomes superconducting (resistance drops to zero) at $T_c = 7.2$ K and in magnetic fields (triangles and filled circles) large enough to keep it normal down to at least 2 K. In this article, the concentration is on nonsuperconducting behavior. Below ~ 8 K, the normal resistivity of Pb in a magnetic field decreases more rapidly than linearly with temperature, and then saturates to a constant value at the lowest temperatures. Fig. 6 shows, in Pd, a more complex low-temperature resistivity than just the Bloch-Gruneisen form; here $\rho(T)$ contains two terms, a term arising from electron-electron scattering, plus an approximately T^5 Bloch-Gruneisen-like term. As T decreases, Figs. 5 and 6 show that the

Fig. 2 Resistivity as a function of temperature for Cu, a metal where the form of the resistivity is similar to that predicted by the Bloch-Gruneisen model.

Fig. 3 Resistivity as a function of temperature for Ni, a metal that becomes ferromagnetic below its Curie temperature of ~ 650 K.

Fig. 4 Resistivity as a function of temperature for a single-crystal sample of Gd, which has a noncubic crystal structure.

Fig. 5 Low-temperature resistivity of Pb, which becomes superconducting (the resistivity drops to zero) in zero magnetic field at ~ 7.2 K. In a magnetic field of 600 Oe, Pb remains normal to the lowest temperature measured in this figure, and the resistivity at the lowest temperatures becomes constant, at a value determined by residual impurities.

temperature-dependent part of $\rho(T)$ eventually becomes smaller than the resistivity due to residual defects, and the measured resistivity (designated as residual resistivity, ρ_0) becomes closely independent of temperature (constant) at a value determined by the nature and concentration of these defects.

If a concentration c of a given defect is added to a “pure” metal, the resulting total resistivity $\rho_T(c, T)$ can often be approximated by simply summing the temperature-dependent resistivity, $\rho_P(T)$, of the ideally pure host metal and a temperature-independent term, $\rho_0(c)$, due to the presence of the defect. This result is called Matthiessen’s rule:

$$\rho_T(c, T) \approx \rho_0(c) + \rho_P(T) \quad (16)$$

Fig. 6 $(\rho - \rho_0)/T^2$ vs T^3 for the transition metal Pd at low temperatures, where ρ_0 is the (constant) residual resistivity. In addition to an approximately T^3 Bloch-Grüneisen-like term, the data contain also a T^2 term due to electron-electron scattering.

Fig. 7 Resistivity vs concentration (c in at.%) for Bi, Pb, Ti, Hg, and Au impurities in Ag, showing the expected linear variation with c , for small c .

The content of Eq. (16) is twofold: (1) the most important feature of the defects is simply their presence, rather than that they vibrate differently from the host atoms; and (2) scattering of electrons from the defects is independent of scattering from the phonons. In practice, Eq. (16) is used to define $\rho_P(T)$, by subtracting the low temperature constant limit of the data, ρ_0 , from the measured $\rho(T)$ for the highest-purity samples available.

For small c , $\rho_0(c)$ is proportional to c , $\rho_0(c) = Kc$. The scale for K is $\mu\Omega \text{ cm at.}\%^{-1}$, with values ranging from $0.1 \mu\Omega \text{ cm (at.}\%)^{-1}$ to $10 \mu\Omega \text{ cm (at.}\%)^{-1}$ for different impurities in different host metals. Fig. 7 shows examples of linear variations of $\rho_0(c)$ with c for dilute Ag-based alloys. Note that K increases with increasing difference between the number of “conduction electrons” for the impurity (Au = 1, Hg = 2, Ti = 3, Pb = 4, and Bi = 5) and for the host metal, Ag = 1. If the values of K for impurity A in host B and for impurity B in host A are closely the same, then the relation between $\rho_0(c)$ and c can be approximated over the whole range of alloy concentrations as

$$\rho_0(c) = Kc(1 - c) \quad (17)$$

In practice, the K values for different pairs of metals are usually different enough that Eq. (17) is only a very rough approximation to reality. Fig. 8 shows an example of experimental data for PdAu alloys.

Careful measurements of $\rho_T(c, T)$ show that Matthiessen’s rule is never exact. The resulting deviations from Matthiessen’s rule (DMR) are defined by the relation

$$\Delta(c, T) = \rho_T(c, T) - \rho_0(c) - \rho_P(T) \quad (18)$$

Such deviations have been studied for a variety of impurities and host metals. $\Delta(c, T)$ usually consists of a low-temperature peak followed by a linear component at high T that can have positive, negative, or zero slope. Figs. 9 and 10 illustrate the forms seen.

Fig. 8 Residual resistivity vs Au concentration C_{Au} for PdAu alloys, showing that the residual resistivity need not be a symmetric function of C_{Au} .

Fig. 9 Deviation from Matthiessen's rule, Δ , vs temperature for three alloys of Al in Ag.

Fig. 10 Normalized deviation from Matthiessen's rule, Δ/ρ_0 , for a series of alloys of Au in Ag.

Pressure

Measurements of ρ are almost invariably made at constant pressure P , usually at atmospheric pressure or in vacuum. Calculations of ρ , in contrast, are normally made by assuming constant volume V . Thus, to compare measurements and calculations, knowledge of how ρ changes with P is required. Studies of $\rho(P)$ are useful for providing such corrections (which are usually small) and also because measuring R is often the easiest way to study phenomena induced by an application of pressure, such as pressure-induced phase transitions. The relative ease of measuring R also makes it one of the properties of choice for studying phase transitions induced by temperature.

Size effects (mean free path)

If a sample wire or film is made so thin that there is a significant probability of electrons being scattered by the sample surface, and if such scattering is at least partly diffuse (i.e., with the final momentum of the scattered electron randomized in direction), then the resistance of the sample will increase due to such scattering. In the simplest case of a thin cylindrical wire of a free-electron metal of diameter d and completely diffuse scattering (i.e., the component of the electron's momentum along the wire or film is randomized by each collision), the total resistance $\rho_T(d)$ can be approximated by the relation

$$\rho_T(d) = \rho_B + (\rho\lambda)/d \quad (19)$$

Here, ρ_B is the resistivity of the bulk material, and $\rho\lambda$ is a constant representative of the particular metal involved, as shown in Eq. (8). If one replaces ρ by the experimental resistivity of the metal at a particular temperature, then λ would be the experimental "mean free path" for free electrons in that metal at that temperature—that is, λ is the typical distance moved between scattering events that significantly change the direction of the electron's momentum. A qualitative insight into Eq. (19) can be obtained by analogy with Matthiessen's rule, wherein the second term of Eq. (19) represents the increase in resistivity when the sample diameter is equal to its mean free path. For partially specular scattering (mirror-like, in which the momentum component along the wire or film remains unchanged), or for the different geometry of a film, the equations are more complex, and the interested reader is referred to the Further reading section. Fig. 11 shows examples of the applicability of Eq. (19) for samples with different amounts of surface specularity.

Fig. 11 $\rho(4.2 \text{ K})/\rho(293 \text{ K})$ vs inverse wire diameter, $1/d$, for a series of Cu wires with surfaces giving different amounts of diffuse scattering ($p = 0$ indicates estimated completely diffuse scattering).

Some related phenomena outside the purview of this chapter

Magnetoresistance

The standard quasiclassical treatment of electrical conduction in metals outlined above can also be used to describe the phenomenon of magnetoresistance in nonmagnetic metals and alloys, as well as the changes in electrical resistivity that occur upon application of an external magnetic field.

Kondo effect

In contrast, this standard quasiclassical analysis always yields, as a low-temperature limit, a constant resistivity, corresponding to the scattering of the conduction electrons by residual impurities. It could, thus, not explain observed deviations from this prediction for some magnetic impurities in nonmagnetic hosts, where the resistivity increases with decreasing temperature. This phenomenon was dubbed the “Kondo effect” when it was explained many years later by Kondo as arising from an anomalous scattering by a dilute concentration of localized magnetic moments in a metallic host. This phenomenon is described elsewhere in this encyclopedia.

Mesoscopic effects

The standard quasiclassical analysis of metallic transport is also unable to explain mesoscopic effects in metallic samples with at least one dimension less than the phase coherence (or dephasing) length, which can be microns or more at cryogenic temperatures. These effects include weak localization in highly disordered metals, and oscillations with the magnetic field in multiply connected samples of size comparable to the dephasing length. To properly treat both the temperature dependence of transport in highly disordered metals, and the oscillatory response to magnetic fields of metallic rings with dimensions smaller than the dephasing length, one must take account of the interference between waves of electrons that follow different trajectories between two points in the sample.

Abstract

Coulomb blockade is a universal phenomenon in electron transport in artificially made nanostructures. It can be understood by a simple and closed reasoning given in this article. We concentrate on big normal Coulomb islands omitting superconductivity and discreteness of electron spectrum. We review the basic concepts of Coulomb blockade, consider the work of generic devices—SEB en SET, master equation approach for single electron transfer. We outline quantum effects and co-tunneling, and shortly review the applications of the phenomenon.

Key points

- The concepts of charge quantization and charging energy
- Single electron box to store quantized charge
- Tunneling rates and master equation to describe the Coulomb-blockaded transport
- The simplest device: Single Electron Transistor
- The typical manifestations of Coulomb blockade phenomenon
- Co-tunneling: a quantum alternative to single-charge tunneling
- Weak Coulomb blockade: if quantum effects are significant
- Possible applications of Coulomb blockade

Introduction

In fact, it is paradoxical that interacting electrons are commonly regarded as non-interacting particles in solid state physics of bulk materials. Doing so, we satisfy the human want for simplification that fortunately can be justified in many cases by physical reasons. The most common physical argument is that in conductors we are not dealing with electrons. Rather, we call “electrons” the quasi-electrons: Landau quasiparticles, charged elementary excitations on the background of a ground state formed by original interacting electrons. The quasi-electrons indeed interact very weakly provided their energies are sufficiently close to the Fermi surface, this is in contrast to the original electrons. The interaction renormalizes their velocities at the Fermi surface, yet this change is not qualitative one. This is why our use of a model of non-interacting electrons usually goes unpunished. The model of non-interacting electrons ceases to work only in isolated cases, that are notoriously difficult to comprehend and quantify. Some of them, like Mott insulator transition, are known for almost a century, yet the progress in this direction remains moderate. Importantly, the progress is restricted to particular cases—the understanding of strongly interacting electrons does not match the universality of noninteracting model.

Surprisingly, the role of interaction in quantum transport is in contrast with that in solid state physics. There is a very common and universal regime where interaction is dominant and non-interacting model makes no sense. This regime is also simple: relevant

and non-trivial predictions can be derived from an unbelievably short, self-contained and closed reasoning that takes charge quantization and associated charging energy as the starting point. This is the Coulomb blockade regime outlined in this article. It occurs in any nanostructure where a place to store an electron—an island—is sufficiently isolated from the leads and/or other islands.

In this article, we concentrate on Coulomb blockade in sufficiently big normal islands. Coulomb blockade is also crucial for quantum dots, where islands are sufficiently small to manifest the discreteness of electron spectrum, as well as for superconducting structures, where the combination of Coulomb blockade and Josephson effect provides a base for modern sophisticated quantum technologies.

Charge quantization and charging energy

To comprehend these concepts, let us consider a many-atom isolated metallic island hanging in vacuum—a setup similar to that of seminal oil drop experiment (Millikan, 1913). The bulk properties of the island should be well described with the non-interacting electron model: the electron-electron interaction suppose to result in a velocity renormalization. Let us however note that the total charge of the island may be non-zero. Since number of elementary particles in the island—protons and electrons—must be integer, this charge is *quantized* amounting to an integer number of elementary charges, $Q = Ne$. Owing to screening, the actual charge is concentrated in a thin layer near the surface of the island not affecting its bulk properties. Abeit the charge Q produces electric field E outside the island, and this costs energy. According to the laws of electrostatics, this energy is readily be expressed via capacitance C of the island,

$$E = \frac{Q^2}{2C} = \frac{e^2}{2C} N^2 \equiv E_C N^2. \quad (1)$$

So if we charge a neutral island with an extra electron, we have to pay the *charging energy* E_C . This energy cost is rising if we put more electrons: we have to supply $E_C N^2 - E_C (N-1)^2 = E_C (2N-1)$ extra energy to add the N th electron. The same goes for the electron extraction. The fact that the addition energy depends on number of particles added is in contradiction with the non-interacting model: Charging energy presents electron-electron interaction. The capacitance scales with the linear size of the island. Owing to this, the charging energy $\propto 1/C$ vanishes in common limit of big number of particles when the energies are counted per particle. However, the charging energy is finite for any finite island.

The addition energy is also contributed by a non-interaction effect: The electron levels in a finite island are quantized with a finite mean level spacing δ_S , and the electron added would go to the first unoccupied level separated by δ_S from an occupied one (Fig. 1b). Let us compare these two contributions: charging energy E_C and the mean level spacing δ_S . Let us take an island of the typical size L . It consists of $N_{at} \simeq (L/a)^3$ atoms, a being the interatomic distance. Since there are several valence electron states per atom and they fill up the energy band $\simeq E_F$, the mean level spacing is estimated as $\delta_S \simeq E_F/N_{at}$. Since the charge e is spread over the size L , Coulomb law delivers the estimate for the charging energy of $e^2/(4\pi\epsilon_0 L)$. We notice that $e^2/(4\pi\epsilon_0 a) \simeq E_F$ for typical metals to arrive at

$$\frac{\delta_S}{E_C} \simeq \frac{E_F L}{e^2 N_{at}} = \frac{E_F a}{e^2} \frac{4\pi\epsilon_0 L}{a N_{at}} \simeq \frac{1}{N_{at}^{2/3}}$$

Thus Coulomb interaction dominates the addition energy provided the island consists of many atoms, $E_C \gg \delta_S$. This discreteness becomes important only for nanostructures consisting of several natural atoms, like a molecule, or comprising an artificial atom, like a quantum dot in a semiconductor heterostructure. To give several numbers, for $L = 100$ nm $E_C \simeq 1$ meV, while $\delta_S \simeq 10^{-8}$ eV: five orders of magnitude difference. In the rest of the article we neglect the discreteness of electron spectrum.

The electron transport to the island is blocked unless the energy of the order of E_C is supplied either by an external voltage source or by a thermal fluctuation. This explains the term *Coulomb blockade*.

Fig. 1 (a) Excess charge in an isolated metallic island produces electric field outside, this costs charging energy. (b) The energy required to put an electron into the island is not just a typical level spacing δ_S : it includes charging energy $E_C \gg \delta_S$.

Fig. 2 Single Electron Box. (a) Setup. (b) Equivalent capacitance circuit (dashed box includes capacitance plates that belong to the island) (c) The charging energy of the single electron box vs. $q = -C_g V_g$. Each parabola corresponds to a charge state with N excess charges. Lowest segments of the parabolas give the minimum energy of the setup and the actual charge state.

Single electron box

The concepts outlined above have been put forward by Kulik and Shekhter (1975) to understand the transport in granular materials composed of a plenty of random and uncontrolled metallic islands. They did not get much popularity till the advance of nano-fabrication permitted realization of controllable setups with a single or several islands of submicrometer size. The basic setup of this kind is called a Single Electron Box (SEB) and has been realized in Lafarge et al. (1991). It consists of a single island and two bulk metallic electrodes: Source and gate. One places the island close to the source electrode to enable electron transfer, while the transfer is not possible between the island and the gate electrode (2 a). The advantage of the setup is the possibility to tune the number of extra electrons in the island changing the potential V_g of the gate electrode with respect to the source (so that $V_s = 0$). Physically, V_g shifts the electrostatic potential of the island with respect to the source, this drives electrons to/from the island. In other words, the gate potential induces charge in the island.

To quantify, note that in a stationary state the number of electrons in the island corresponds to the minimum electrostatic energy. The equivalent electrostatic circuit of the setup is given in Fig. 2b. It consists of two capacitors: C , which is in between the island and the source, and C_g , which is in between the island and the gate. The charges at the plates of these capacitors are $\pm q_{1,2}$ respectively. The total charge of the island is $eN = q_1 - q_2$. The electrostatic energy consists of the energy accumulated in these capacitors and the work done by the voltage source to transfer the charge q_2 to the gate electrode, $-q_2 V_g$. Minimization in q_2 yields

$$E_{el} = E_C \left(N - \frac{q}{e} \right)^2; E_C \equiv \frac{e^2}{2(C + C_g)} \quad (2)$$

where we skip terms not depending on N and introduce a handy notation: a charge induced in the island by the gate, $q \equiv -C_g V_g$. This *induced charge* is a continuous variable in contrast to the quantized charge eN of the island. If N were continuous, the charge of the island would have been q corresponding to $E_{el} = 0$.

To reveal the effect of charge quantization, we plot in Fig. 2c the energy vs. q for various discrete N . Each N gives a parabola that reaches zero minimum at $q_N = eN$. The ground state energy is defined by lowest segments of the parabolas. The minimum energy thus occurs at different discrete $N(q) = \lfloor q/e + 1/2 \rfloor$, where the square brackets denote the floor of a continuous number. $N(q)$ is thus a step-like function of q . We note e-periodicity: The minimum energy along with all system properties is periodic in q with a period e .

Let us understand the requirements on the connection between the island and the source electrode for charge quantization to occur. It is clear that even a thinnest metallic shortcut connecting the two would kill the effect: in this case, the charge in the island does not have to take integer values since there is no natural separation between electron states in the island and in the electrode and an electron has to be localized neither in the island nor in the electrode. In practice, the sufficient isolation can only be provided if the two are separated by an insulating layer the electrons can tunnel through. If this layer is thick exceeding by far the typical electron wave length, the tunneling is exponentially slow and the resulting currents are too small to measure. The thicknesses of the insulating layers should be of the order of the wave length, that is, for good metals, several interatomic distances. The native oxide layers at aluminum provide most frequent practical solution. However, it is not a thickness of the layer that is relevant for the absence or presence of charge quantization. Rather, it is the total conductance G of the resulting tunnel junction in units of conductance quantum $G_Q \equiv e^2/\pi\hbar$. This follows from a simple qualitative reasoning that combines classical and quantum approaches. The Heisenberg uncertainty relation $\Delta E \Delta t \gtrsim \hbar$ implies that the energy difference is well-defined provided the typical time scale at which it is acquired is sufficiently long. For our situation, $\Delta E \simeq E_C$, while the time scale is a typical RC time of capacitor discharge through the junction, $\Delta t \simeq C/G$. Substituting this into the uncertainty relation, we obtain that the well-defined charge quantization requires $G \ll G_Q$. We will assume this to be fulfilled till the Sections “Coulomb oscillations and staircase” and “Quantum effects” of this article where we discuss the effects of quantum fluctuations on Coulomb blockade: weak Coulomb blockade and co-tunneling.

Single electron transistor

The appeal of Coulomb blockade systems is that the electrons under most general circumstances are transferred one by one: Most of the time the islands of a system are in a well-defined charge state, the most probable change of its state involves a single electron

Fig. 3 Single Electron Transistor (SET). The electron transport from L to R requires change of the charging state N and is influenced by the gate voltage V_g . The arrows give four possible single-electron transfers in SET (from/to left/right).

transfer in one of the tunnel junctions. We exemplify the notion of single electron transfers describing in detail the simplest and by far most popular Coulomb blockade device, single electron transistor (SET). It is. The concepts outlined—the energetics of the transfers, master equation approach to their dynamics, the energy dependence of the tunneling rates—are straightforwardly applied to more complex Coulomb blockade systems.

The design of the SET (Averin and Likharev, 1986; Fulton and Dolan, 1987, Fig. 3) is very similar to that of the SEB with an important distinction: an extra transport electrode contacting the island. Like any transistor, SET has three electrodes. Two electrodes, R and L , source and drain, are the transport ones: an electric current from R to L if there is a voltage difference between those. This current is affected by the potential of the gate electrode. The electrostatic energy for a given charge configuration involves all the capacitances C_R , C_L , C_g and voltages V_R , V_L , V_g being present and is given by an expression similar to that of SEB.

$$E_{el} = E_C(N - q/e)^2; E_C = \frac{e^2}{2C_\Sigma}. \quad (3)$$

where the total capacitance of the island $C_\Sigma = C_R + C_L + C_g$ is contributed by all capacitors as well as the induced charge $q = C_R V_R + C_L V_L + C_g V_g$.

Let us list all possible processes of single electron transfer in a SET given it is in the charge state N . The number of charges can change in four ways (Fig. 3): Extra electron can jump into the island either from the left (FL) or from the right (FR) electrode, with N changing to $N + 1$. Alternatively, an electron can also leave the island either to the left (TL) or to the right (TR), with the change $N \rightarrow N - 1$. Each process at a given N is characterized by an energy difference between final and initial state. This energy difference involves the difference of electrostatic energy given by Eq. (3) as well as the energy cost associated with addition/extraction of an electron $\pm eV_i$ to/from the corresponding electrode. Let us list the energy differences associated with all four processes,

$$\begin{aligned} FL : \Delta E_{FL}(N) &= E_{el}(N + 1) - E_{el}(N) - eV_L; \\ TL : \Delta E_{TL}(N) &= E_{el}(N - 1) - E_{el}(N) + eV_L; \\ FR : \Delta E_{FR}(N) &= E_{el}(N + 1) - E_{el}(N) - eV_R; \\ TR : \Delta E_{TR}(N) &= E_{el}(N - 1) - E_{el}(N) + eV_R. \end{aligned}$$

Here, the electrostatic energy change reads

$$E_{el}(N \pm 1) - E_{el}(N) = 2(\pm N + 1/2 \mp q/e)E_C.$$

Let us concentrate at zero temperature limit where the tunneling electron can gain no energy from heat. In this case, an electron transfer can only occur if the corresponding energy difference is negative, $\Delta E < 0$: Indeed, the energy can only be dissipated, and not gained. This simple inequality governs the transport in Coulomb blockade systems and defines the regions of parameters—gate and transport voltages—where the electron transport proceeds in a certain way, that is, the regions of different transport regimes.

The simplest, and the most important transport regime is the Coulomb blockade itself. In this case, in the given charge state N all four single-electron processes are forbidden. This requires all four energy differences to be positive,

$$\Delta E_{TL, FL, TR, FR}(N) > 0. \quad (4)$$

Since the charge state does not change and no electron transfers take place, no current is expected in Coulomb blockade regime at zero temperature.

To sketch the parameter regions where Coulomb blockade takes place, we assume symmetric capacitors $C_R = C_L$ and antisymmetric bias voltage $V_L = -V_R = V/2$ (in such setup, the induced charge q conveniently does not depend on bias voltage). For $N = 0$, the four conditions (4) become $2E_C(\pm + q/e) \pm eV/2 > 0$. In the V - q plane, each condition corresponds to a slanted straight line. Four such lines carve a diamond in V - q plane where all four conditions are fulfilled. For $N = \pm 1, \pm 2, \dots$ the corresponding diamond is shifted by $\pm e, \pm 2e, \dots$ along q -axis (Fig. 4) representing the e -periodicity in induced charge q . Such periodic diamond pattern of a suppressed current is typical for various systems and nanostructures exhibiting Coulomb blockade.

Another example transport regime is when the electrons go one by one from the left to the right. Two transfers are allowed: one from the left at N , and one to the right at $N + 1$, and thus have negative energy differences,

Fig. 4 Coulomb diamonds in SET. The transport is blocked inside white diamonds corresponding to. Light gray: the region where the one-by-one transport cycle takes place.

$$\Delta E_{FL}(N) < 0; \Delta E_{TR}(N+1) < 0.$$

while all other possible processes at N and $N+1$ are blocked and thus have positive energy differences. In particular,

$$\Delta E_{FL}(N+1) > 0.$$

assures that the electrons really go one-by-one: the second electron cannot enter the island while the extra electron is there. This regime is realized in light-gray diamonds in Fig. 4. They have the same shape as the Coulomb diamond and are shifted in such a way that a diamond where $N, N+1$ states participate in the transport is adjacent to the Coulomb diamonds with N and $N+1$. This pattern repeats itself for higher diamonds: a diamond inherits the participating charging states from the lower diamonds adjacent to it. This sets various transport regimes in V - q plane.

The electron transport in Coulomb blockade system can be accurately quantified within the master equation approach. For a SET, one can assume that at any given moment of time it is in a given charge state N . This is a classical state rather than a quantum one, no quantum superpositions are permitted. The transitions between the states proceed by means of electron transfers. A certain transfer is a stochastic event that happens with the probability per unit time given by the corresponding rate Γ that depends on the charging state. The probability per unit time for this transfer. Since the dynamics are random, the approach has to be probabilistic. The SET is described by probability $p(N)$ to be in the state N . The probability is obtained from the master equation:

$$\begin{aligned} \frac{d}{dt} p_N(t) = & -(\Gamma_F(N) + \Gamma_T(N))p_N(t) + \\ & \Gamma_F(N-1)p_{N-1}(t) + \Gamma_T(N+1)p_{N+1}(t). \end{aligned} \quad (5)$$

Here, $\Gamma_{F,L}$ are the total rates to go from/to the island,

$$\Gamma_F = \Gamma_{FL} + \Gamma_{FR}; \Gamma_T = \Gamma_{TL} + \Gamma_{TR}.$$

Here, the probability change per unit time is given by the time derivative at the l.h.s. and is contributed by two groups of terms: Outgoing and incoming. Outgoing terms are due to transfers from the state N to any other states. For a SET, these states can be either $N-1$ or $N+1$, the corresponding rates adding up. The contribution to the derivative is negative and proportional to the probability to be in the initial state p_N : The system must be in this state for the process to occur. Incoming terms are due to transfers any initial state to the state N . Their contribution to the derivative is positive and proportional to the probabilities to be in the initial states and the corresponding rates: for initial states $N+1$ and $N-1$ the rates are respectively $\Gamma_F(N+1)$ and $\Gamma_T(N-1)$.

For stationary conditions (stationary voltages) a stationary solution of the master equation, $p_N^{(0)}$ is readily obtained from the master equation with zero l.h.s. and the condition that the probability to be in any state must total to 1, $\sum_N p_N = 1$.

The currents are also obtained from the probability balance. For instance, the current through the left junction is contributed by “from the left” processes with positive sign and by “to the left” processes with negative sign, so that

$$I_L = e \sum_N [\Gamma_{FL}(N) - \Gamma_{TL}(N)] p_N. \quad (6)$$

Similarly, for the current through the right junction we obtain

$$I_R = e \sum_N [\Gamma_{TR}(N) - \Gamma_{FR}(N)] p_N.$$

By virtue of charge conservation, the stationary currents $I_L = I_R$. This is automatically fulfilled if p_N is the stationary solution of the master equation, $p_N = p_N^{(0)}$.

To use the master equation for the quantitative description of single-electron transport, we must know the rates at given setting of the gate and bias voltages. The rates could be computed from the tunneling Hamiltonian, but in fact could be derived from the following elementary reasoning. Let us consider a tunnel junction between two leads and forget about Coulomb blockade for a moment. If a voltage difference at $k_B T = 0$ is applied to the leads, the electrons in the energy strip of the width eV can go from the left to the right. The number of electron transfers per unit time is given by the transfer rate Γ so it is related to the current simply by $\Gamma = I/e$. From the other hand, $I = GV$ by definition of the junction conductance G . Therefore $\Gamma = eVG/e^2$, provided eV is positive. Note that $eV = -\Delta E$, the energy difference associated with this transfer that determines the energy strip available for tunneling. If Coulomb blockade is present, the tunneling electron must perform some extra work to charge the capacitors of the SET, so $\Delta E \neq -eV$ yet still determines the width of the relevant energy strip. So that the rate of a single electron transfer in a junction of conductance G accompanied by the energy change ΔE is generally given by

$$\Gamma = \frac{G}{e^2} (-\Delta E) \Theta(-\Delta E) \quad (7)$$

at $k_B T = 0$. At finite temperature this is modified to

$$\Gamma = \frac{G}{e^2} \frac{\Delta E}{\exp\left(\frac{\Delta E}{k_B T}\right) - 1}. \quad (8)$$

That is, the thermal fluctuations provide a finite rate even for $\Delta E > 0$. This rate is exponentially small provided $\Delta E \gg k_B T$.

The concepts discussed in this Section—energy differences in capacitive networks, the transfer rates determined by these differences, the master equation incorporating the rates—form a closed scheme that can be readily applied to quantify the transport in any arbitrary complex Coulomb blockade system.

Coulomb oscillations and staircase

Here, we discuss the two common and prominent transport signatures that manifest Coulomb blockade in SET. The first one called *Coulomb oscillations* is observed in zero-voltage conductance of the device. At zero bias voltage and $k_B T \ll E_C$ the SET is in Coulomb blockade regime except the points $q/e = 1/2 + N$ where diamonds corresponding to charging states N and $N + 1$ touch each other at $V = 0$ line (crossed circles in Fig. 4). In these points, the energies of two charging states are the same and the minimum addition energy $\Delta_{\min} = 2E_C(1/2 - |q|/e)$ vanishes enabling the electron transport at $k_B T \simeq \Delta_{\min}$, and the conductance peaks. The peak shape near the degeneracy point is given by $G(q) = G_{\max}(\Delta_{\min}/k_B T) / \sinh(\Delta_{\min}/k_B T)$, where $G_{\max} = (1/2)G_L G_R / (G_L + G_R)$. One thus observes a periodic (oscillating) pattern of equidistant peaks, with a period e along q axis. With increasing temperature, the peaks first become wider and then merge at $k_B T \approx 0.15E_C$ (Fig. 5). However, the periodic modulation—Coulomb oscillations—remains visible up to $k_B T \simeq 0.7E_C$. At $k_B T \gg E_C$ charging energy becomes irrelevant, and Ohm's law is restored with the conductance $G_{\infty} = G_L G_R / (G_L + G_R)$. Note that $G_{\infty} = 2G_{\max}$. This is because at the peak the electrons tunnel one-by-one, an extra electron blocks further transfers, while at high temperatures no blocking takes place. This implies there is a temperature range where typical conductance changes from $G_{\max}$. Indeed, in the temperature range $1.5 < k_B T/E_C < 4$ the conductance loses sensitivity to the gate

Fig. 5 Coulomb oscillations. A periodic pattern of zero-voltage conductance of a symmetric SET vs. the charge induced at different temperatures. $k_B T/E_C = 0.01$ for the thick curve and ranges from 0.1 to 2.0 with step 0.1 for subsequent curves.

voltages remaining sensitive to temperature (Fig. 5). Thus, the SET, and the Coulomb blockade systems in general, can be used as a precise thermometer (Meschke et al., 2016) in this temperature range.

Another signature of Coulomb blockade is observed upon increasing the bias voltage at fixed gate voltage. As seen in Fig. 4, the number of charge states available for transport at $k_B T \ll eV$ increases with increasing the voltage. Any time a new state becomes available, the differential conductance $G(V)$ exhibits a jump—this pattern is called *Coulomb staircase*. There are two equidistant series of the voltage values at which a new state becomes available, special voltages

$$eV_{\text{special}} = 4E_C \left(M + \frac{1}{2} \pm \frac{q}{e} \right), \quad (9)$$

M being integer and $\pm$ corresponding to a new transfer through the right (left) junction. These values are given by black circles in Fig. 4 at a dashed line corresponding to $q = 0.3$.

There is a cusp in the current—jump in the differential conductance—at any special voltage for any SET. However, if the conductances of two tunnel junctions are comparable, the cusps are hardly visible in a I - V curve while sufficiently pronounced in the differential conductance (Fig. 6, upper pane).

The Coulomb staircase comes into full beauty if the junction conductances differ by more than an order of magnitude, as illustrated in Fig. 6, lower pane. The cusps are clearly visible in I - V curve and develop into characteristic smooth steps separated by $4E_C/e$ in voltage. Only one cusp series is visible, corresponding to new transfers via the most conducting junction. The current jumps are explained by the fact that the charging state is set by the most conducting junction while the current is determined by the transfers through the least conducting junction. The change of the charging state thus gives a jump in ΔE and the step in the current. The step is rounded at the voltage scale $e\Delta V/E_C \simeq G_{\text{small}}/G_{\text{big}}$.

In any case, at bigger voltages, above E_C/e , the current tends to Ohm's law $I = G_{\infty} V$ since the big voltage drops involved mask any manifestation of single-charging phenomena. It is interesting to note that the best fit is provided by an off-set Ohm's law $I = G_{\infty}(V - 2E_C/e \text{sgn}(V))$. This is used for estimations of the charging energy for concrete devices.

Fig. 6 Coulomb staircase. Upper pane: $G_L = G_R$, $q = 0.3e$. Solid: I - V curve. Dashed: the corresponding differential conductance gives a jump at special values of the bias voltage. The jumps are slightly rounded by finite temperature ($k_B T = 0.01 E_C$). Lower pane: Coulomb staircases with $G_L = 100 G_R$ and $G_L = 0.01 G_R$ ($q = 0.3e$). Each cusp in the current is followed by a the step-like increase. Only one series of special voltages is visible for each curve. Dotted line: Ohm's law.

Quantum effects

As outlined, the concept of Coulomb blockade is classical in nature involving single-electron transitions between well-defined charge states. This concept is valid in the limit of low tunneling conductances $G \ll G_Q$. The concept does not fit the reality precisely at any finite G : the quantum effects mix up the charge states so that the ground state of a Coulomb blockade system does not have a definite charge, and provide the collective electron transfers in Coulomb blockade regime, so-called co-tunneling events.

Let us consider quantum effects in a SEB that is in the ground state with $N = 0$. An electron transfer between the island and would bring the system to a state with $N = \pm 1$ and an electron-hole pair whose components are in the lead and in the island, respectively. This state has a higher energy $E^{(\pm)} \pm \xi \simeq E_C$, $E^{(\pm)}$ being the charging addition/extraction energy, ξ being the energy of the electron-hole pair. Therefore, the transfer cannot actually occur. Nevertheless, by virtue of Heisenberg uncertainty principle, the SEB can enter this state for a short time $t_H \simeq \hbar/E_C$ with the rate Γ . This implies that the true ground state of the single electron box is not an eigenstate of charge anymore: there is a finite probability to catch the SEB in an excited charging state $N = \pm 1$, $p_{\pm 1} \simeq \Gamma t_H \simeq G/G_Q$. Second-order perturbation calculation yields

$$p_{\pm 1} = \frac{\hbar}{2\pi} \int \frac{\Gamma(-\xi) d\xi}{(E^{(\pm)} + \xi)^2} = \frac{G}{2\pi^2 G_Q} \int_0^\infty \frac{\xi d\xi}{(E^{(\pm)} + \xi)^2}, \quad (10)$$

the integration is over the energies of all possible electronhole pairs, $\Gamma(E)$ is given by Eq. (7). We give the expression for average charge representing a smoothing quantum correction to the classical step-like N - q relation,

$$\delta\langle N \rangle = p_1 - p_{-1} = \frac{G}{2\pi^2 G_Q} \ln \left(\frac{1/2 + q/e}{1/2 - q/e} \right) \quad (11)$$

(see Fig. 7) A special feature is that the integral diverges at low energies provided $E^\pm \rightarrow 0$, this corresponds to $q \rightarrow \pm e/2$. Indeed, the correction to average charge formally diverges at $q \rightarrow \pm e/2$, at the degeneracy of two charging states. This indicates that the perturbation theory is no good at tiny energy scale $E^\pm \simeq E_C \exp \{-G/(2\pi^2 G_Q)\}$. This energy range has been inspected in Matveev (1991) where the similarity with a Kondo-like complex many-body problem has been revealed. The Coulomb blockade Kondo has been experimentally investigated in Ifitkhar et al. (2015).

To fully understand the Coulomb blockade phenomenon, it is constructive to access the opposite limit of large conductances $G \gg G_Q$ —the limit of weak Coulomb blockade. Here, it becomes important that a connector between the island and the lead does not have to be a tunnel junction as in the opposite limit. Rather, the connector is characterized by a set of transmission coefficients T_p in its spinsplit transport channels. The influence of the connector on Coulomb blockade in the island depends on the details of the transmission coefficients rather than on the total conductance $G = \frac{G_Q}{2} \sum_p T_p$ only. A simple signature of Coulomb blockade in the ground state of a SEB is the e -periodic q dependent part of the ground state energy. As we have seen, in the limit of vanishing conductance, this part is $\simeq E_C$. The analysis (Nazarov, 1999) shows that a typical spread $\tilde{E}_C$ of the q -dependent part is suppressed by transmission and is estimated as

$$\frac{\tilde{E}_C}{E_C} = \prod_p \sqrt{1 - T_p} \quad (12)$$

This shows that Coulomb blockade, although weakened, survives at any connector, unless one of the transmission is ideal, $T_p = 1$. At a given transmission distribution, $\tilde{E}_C$ is exponentially suppressed. For a tunnel junction where all $T_p \ll 1$, $\tilde{E}_C/E_C \simeq \exp(-G/G_Q)$, while for a diffusive connector of the same conductance $\tilde{E}_C/E_C \simeq \exp(-\pi^2 G/4G_Q)$.

The above expression gives only a leading order estimate of the q -dependent part of the ground state energy. To get the details, and in particular the form of the q -dependence, one needs the full solution of a complex many-body problem. That had been sought for almost 20 years and has been found in Lukyanov (2007). According to Lukyanov (2007), the q dependence is cos-like in the leading order in G ,

Fig. 7 Quantum fluctuations—virtual transitions to other charge states—smoothen the step-like features in N - q relation. Dashed line is $G = 0$ limits, two solid curves correspond to $G = 0.5$ and $0.25 G_Q$.

$$E(q) = 4E^*(1 - \cos(q/e)); \quad E^* = \tilde{E}_C(G/\pi G_Q)^2. \quad (13)$$

The weak Coulomb blockade is a manifestation of a many-body virtual tunneling process called Korshunov instanton (Korshunov, 1987). This process is a phase slip whereby the total wave function of the island is shifted by 2π shift. It is worth noting that the number N of the particles is a canonically conjugated quantum variable to this phase. This becomes especially relevant in superconducting context where it enables quantum applications of superconducting Coulomb blockade devices. However, it is also manifested for normal metal islands, see Jezouin et al. (2016) for experimental verification.

The Korshunov instanton is a close relative of a real process producing so-called leviton excitations (Keeling et al., 2006). The levitons are generated when a carefully engineered voltage pulse, corresponding to a 2π phase shift, is applied to a quantum connector. The levitons have been confirmed experimentally in Dubois et al. (2013). Whereas the leviton is an excitation of electron systems, the Korshunov instanton is a virtual process governing the charge quantization.

Co-tunneling

An old joke likens classical physics to a totalitarian regime where every detail is unambiguously determined by the regulations—physical laws. Quantum physics in this joke presents a more liberal society where everybody is free to get around the regulations—unless those are not fundamental laws. The tunnel processes involving many electrons—co-tunneling processes (Averin and Nazarov, 1990)—under Coulomb blockade conditions provide a rather explicit illustration of this joke.

Let us concentrate on a SET in Coulomb blockade regime at vanishing temperature with a small bias voltage. On a classical level of single electron transfers, the current cannot flow since the transfers are forbidden by energy conservation. On a quantum level, one envisages a combined process where the tunneling of an electron from the left is immediately followed by the tunneling of another electron to the right. In the resulting state, the island charge does not change. However, one electron charge has been transferred from the left to the right producing a current: two electrons have successfully co-operated to get around an energy restriction imposed on single electron transfers. Let us start with a cartoon which will give us an order-of-value estimations of such co-tunneling rates. Electrons want to get from the left to the right (Fig. 8a). They would do it with a typical rate Γ_{FL} . They can not tunnel by virtue of energy conservation: They have to pay charging energy E_C which they do not possess. The cartoon is that the energy conservation is not imposed instantly: the electron may stay in the island during Heisenberg uncertainty time $t_H \simeq \hbar/E_C$ even if the energy conservation forbids a permanent stay. This gives a small but finite chance for the co-tunneling: jump the right junction. This intermediate state is virtual jump the right junction. This intermediate state is virtual rate to the right in this virtual state is thus Γ_{TR} . The chance to realize co-tunneling during the short stay is therefore $\Gamma_{TR}t_H \ll 1$. Multiplying the chances, we get the following estimation,

$$\Gamma_{cot} \simeq \Gamma_{FL}\Gamma_{TR} \frac{\hbar}{E_C}$$

Since a typical estimation of single-electron rate is $\Gamma_{se} \simeq G/C \simeq GE_C/e^2$, we can present this as

$$\Gamma_{cot} \simeq \Gamma_{se} \frac{G}{G_Q}. \quad (14)$$

so that the co-tunneling is essentially less probable than single-electron tunneling provided $G \ll G_Q$, the same condition that assures the presence of Coulomb blockade. At $G \simeq G_Q$ the co-tunneling and similar multi-particle processes become as important as single-electron ones, resulting in corruption and vanishing of Coulomb blockade.

We can make a better cartoon if we take into account the details of the virtual and the final state. Each transfer produces an electron-hole pair as shown in Fig. 8b with positive energies $\xi_L = \varepsilon_1 + \varepsilon_2$, $\xi_R = \varepsilon_3 + \varepsilon_4$. After two electron transfers, the SET is in the final state with four excitations: a hole in the left electrode, an electron and a hole in the island, and an electron in the right electrode. We count the energies of these excitations from the corresponding Fermi levels, so that all $\varepsilon_i > 0$. The energy conservation dictates

Fig. 8 Co-tunneling in SET. (a) Co-tunneling in SET: simultaneous transfer of two electrons in two junctions is not forbidden by energy conservation. (b) Energy diagram for inelastic co-tunneling: two electron-hole pairs left in the final state. Gray: filled electron states.

that $\xi_L + \xi_R = \sum \varepsilon_i = eV$, so each $\varepsilon_i < eV$. Since the number of electron states in an energy strip is proportional to the width of the strip, the number of states available is reduced by a factor $\simeq (eV/E_C)^2$. The same factor reduces the rate in comparison with the estimation (14)

$$\Gamma_{cot} \simeq \frac{G_L}{G_Q} \frac{G_R}{G_Q} \left(\frac{eV}{E_C} \right)^2 eV. \quad (15)$$

This consideration is relevant at vanishing temperature $k_B T \ll eV$. In the opposite case $k_B T \gg eV$, the excitations can appear in the energy strip of the width of $k_B T$, this gives the rate of thermally activated co-tunneling,

$$\Gamma_{cot} \simeq \frac{G_L}{G_Q} \frac{G_R}{G_Q} \left(\frac{k_B T}{E_C} \right)^2 k_B T. \quad (16)$$

The thermally-activated processes can proceed in both directions, from the left to the right as well as from the right to the left. The rates in both directions differ only by a small factor $\simeq eV/k_B T$. Therefore the current can be estimated as $I_{cot} \simeq V(G/G_Q)^2 (k_B T/E_C)^2$. Two-electron co-tunneling is an inelastic process, and leads to non-linear and/or temperature-dependent I - V curves.

Let us quantify the co-tunneling rates in a SET setup. General rules of quantum mechanics imply that the transition rate between initial state i and final state f is given by the Fermi Golden rule the square of transition matrix element M_{if} or amplitude, between the states. In our case, the amplitude involves the tunneling matrix elements of both transfers and the inverse energies of the virtual states,

$$M_{if} = \sum_v \frac{H_{iv}^{(int)} H_{vf}^{(int)}}{E_i - E_v}. \quad (17)$$

Note that each final state can be reached via two possible virtual states that differ in the order of two single-electron transfers. If the tunneling through the left junction comes first, the charge of the island changes from N to $N + 1$. The energy of the resulting virtual state v_+ with respect to initial one is $E^{(+)} + \xi_L$. Alternatively, the transfer through the right junction happens first changing the charge of the island to $N - 1$ so the energy of alternative state v_- reads $E^{(-)} + \xi_L$. The resulting amplitude is thus the sum of these two possibilities. Squaring the amplitudes and implementing Eq. (7) for the single-electron rate yields

$$\Gamma_{cot} = \frac{\hbar}{2\pi} \int d\xi_L d\xi_R \Gamma_L(-\xi_L) \Gamma_R(-\xi_R) \times \left(\frac{1}{E^{(+)} + \xi_L} + \frac{1}{E^{(-)} + \xi_R} \right)^2 \delta(\xi_R + \xi_L - eV). \quad (18)$$

This gives the co-tunneling from the left to the right, the cotunneling in opposite direction is obtained by the replacement $eV \rightarrow -eV$.

Let us elaborate on two simple limits. For $eV \gg k_B T$, the co-tunneling proceeds only in the energetically favorable direction. The integration domain is restricted by $\xi_{L,R} > 0$ and the expression is valid in the whole Coulomb diamond restricted by $E^{(\pm)} > 0$. The single-electron rates in this situation read $\Gamma_{L,R}(-\xi) = G_{L,R}/e^2 \xi$, and the integration can be performed analytically to give

$$I_{cot}(V) = \frac{\hbar G_L G_R V}{2\pi e^2} \left[\left(1 + \frac{2}{eV} \frac{E^{(+)} E^{(-)}}{E^{(+)} + E^{(-)} + eV} \right) \times \ln \left(1 + eV/E^{(+)} \right) \left(1 + eV/E^{(-)} \right) - 2 \right]. \quad (19)$$

Another significant limit is that of relatively small voltage $eV \simeq k_B T \ll E^{(\pm)}$. To integrate, we disregard the dependence of energy denominators on $\xi_{L,R}$ so the rate reduces to

$$\Gamma_{cot}^{LR} = \frac{\hbar G_L G_R}{12\pi e^4} \left(\frac{1}{E^{(+)}} + \frac{1}{E^{(-)}} \right)^2 \frac{(eV)((eV)^2 + (2\pi k_B T)^2)}{1 - \exp(-eV/k_B T)},$$

and $\Gamma_{cot}^{RL}(V) = \Gamma_{cot}^{LR}(-V)$. The co-tunneling current is the difference of these two rates,

$$I(V) = e(\Gamma_{cot}^{LR} - \Gamma_{cot}^{RL}) = \frac{\hbar G_L G_R}{12\pi e^2} \left(\frac{1}{E^{(+)}} + \frac{1}{E^{(-)}} \right)^2 \times V((eV)^2 + (2\pi k_B T)^2), \quad (20)$$

in full accordance with the above qualitative estimations. The typical V^3 dependence of co-tunneling current has been experimentally verified rather early (Geerligs et al., 1990b). However, the observed current was roughly a factor of two larger than one predicted by Eq. (20). This discrepancy was explained in Laakso et al. (2010) by overheating of the SET island to effective temperatures $k_B T \simeq eV$.

There are more interesting and complex co-tunneling processes. To protect the Coulomb blockade in devices against undesired multi-electron processes, one can replace a SET with a 1 d array of N junctions and $N - 1$ islands (Fig. 9a) To transfer a charge across an array of N junctions, N electrons should co-operate jumping simultaneously. Such process creates $2N$ excitations in the final state. Multiplying rate suppression factors for each junction and for each excitation brings us to the following estimate (with the energy available for co-tunneling being $\Delta E \simeq \max(eV, k_B T)$)

$$\Gamma_{cot} \simeq \left(\frac{G}{G_Q} \right)^N \frac{1}{E_C/\hbar \Delta E \simeq E_C}; \quad (21)$$

Fig. 9 Complex co-tunneling processes. (a) A charge transfer in a four-junction array under Coulomb blockade conditions. Four electron-hole pairs are left in the final state. (b) Cotunneling enables transport of artificial excitons—electron-hole pairs in capacitively coupled arrays.

$$\Gamma_{cot} \simeq \left(\frac{G}{G_Q}\right)^N \left(\frac{\Delta E}{E_C}\right)^{2N-2} \frac{\Delta E}{\hbar}, \Delta E \ll E_C \quad (22)$$

As far as $G \ll G_Q$, the rate of N -electron co-tunneling is much smaller than that of two-electron one.

Co-tunneling not only spoils Coulomb blockade: it may provide novel device functionalities. To demonstrate this, let us place two 1D Coulomb arrays close to each other making a substantial capacitive coupling between neighboring islands of opposite arrays (Fig. 9b). There is no electric connection between the arrays, and each of them is connected to its own transport electrodes. With proper gate voltages, one induces charges of opposite polarities in these opposite arrays. The Coulomb attraction between these charges of opposite sign forms artificial excitons: bound states of electron and hole (Averin et al., 1991). To set these artificial excitons into motion, small bias voltages are applied to the arrays. The exciton moves in this double array as a whole by means of a co-tunneling process made of two simultaneous electron transfers in opposite directions and opposite arrays. In a wide window of bias voltages, the currents in both electric circuits are therefore same in amplitude and opposite in direction. This is a current copier experimentally realized in Matters et al. (1997).

Until now we assumed that at least two electrons participate in a co-tunneling process. However, there is a chance that the same electron that enters the island from the left tunnels out to the right thereby completing the co-tunneling process without creating an electron-hole pair in the island. The chance for this seems negligible: it must be smaller than the inelastic cotunneling rate by a factor of number of states in the energy window of the order of E_C . The electron states in the island are discrete with average spacing $\delta_S \ll E_C$. Thus, the same-electron rate is estimated as $\Gamma_{el-cot} \simeq \Gamma_{cot}(\delta_S/E_C)$. However, the process involving the same electron is elastic: no excitations are there in the island in the final state, and the electron transferred to the right has the same energy as the incoming electron. This lifts the extra factor $(eV/E_C)^2$ which suppresses the inelastic co-tunneling at small bias,

$$\Gamma_{el-cot} \simeq G_{el}V/e; G_{el} \simeq \frac{G_L G_R}{G_Q} \frac{\delta_S}{E_C}. \quad (23)$$

Comparing this with Eq. (15), we find that the elastic cotunneling dominates at sufficiently low energies $\Delta E \leq \sqrt{\delta_S E_C}$. This has been confirmed experimentally (Hanna et al., 1992). The elastic cotunneling is important for quantum dots where $\delta_S \simeq E_C$.

Applications

Before discussing the applications of Coulomb blockade, let us mention the major obstacle hindering those: background charges. From the above discussion, one can get an impression that the charge state is unambiguously defined by gate voltages. However, the gate electrodes is not the only source of the induced charge. In a realistic nanostructure, there are always some stray charges located in insulating parts of the structure: either in tunnel barriers of the junctions or in the substrate. Usually, these charges are ionized impurities inevitably present in any material. All together, these random sources produce a background charge q_i that adds to the charge induced by the gate electrode in the island i . The absolute amount of the excess charges does not matter, since the charging

energy is periodic in $N, q/e$. Therefore one can regard the q_i to be uniformly distributed in the interval $(-|e|/2, |e|/2)$. In principle, the background charge can be always compensated by the proper shift of the gate voltage, and this goes almost automatically for a single-island SET. However, N -island system requires a complex and hardly practical tuning on N independent gate voltages. Another aspect is that the configuration of the background charges changes spontaneously at some large time scale related to the motion of these charged impurities. This produces a low-frequency charge noise affecting the work of Coulomb blockade devices.

The most successful and promising application of Coulomb blockade concerns the artificial quantum systems for quantum information processing made in superconducting nanostructures and based on combination of Josephson effect and Coulomb blockade (Wendin, 2017). This topic is bulky and certainly beyond the scope of the present article. Let us however spend several lines to explain how this works (Nazarov and Blanter, 2009) taking a SEB as an example. Superconductivity brings about two distinct points: i. Lowlying energy excitations—electron-hole pairs—are absent in gapped superconductors. Owing to this, there is a unique quantum state $|N\rangle$ corresponding to a charging state with N extra electrons in the island; ii. Tunneling between the island and the lead provides a quantum-coherent transfer of a Cooper pair—two electrons—not accompanied by any dissipation and/or change of a quantum state. This provides mixing of the quantum states with different N and their superpositions. The quantum Hamiltonian describing SEB consist of two parts:

$$\hat{H} = \sum_N E_C (N - q/e)^2 |N\rangle\langle N| + \frac{E_J}{2} (|N\rangle\langle N+2| + |N\rangle\langle N-2|). \quad (24)$$

Here, the first part is the Coulomb energy given by Eq. (2). Second part is Cooper-pair tunneling between the lead and the island characterized by the Josephson energy E_J . A great variety of competing Josephson qubit designs have been proposed and realized (Nazarov and Blanter, 2009). At the moment, the transmon (Koch et al., 2007) design seems to win, insensitivity to the charge noise mentioned being one of its major advantages.

Since early days of Coulomb blockade, a substantial research effort has been devoted to realization of robust metrological standard of electric current. Such device is fed by a voltage signal with frequency f and provides the current $I = \pm ef$, that is, ± 1 electrons per cycle. Early designs included single-electron turnstile, where electrons have been pulled by a bias voltage (Geerligs et al., 1990a), and single-electron pump (Pothier et al., 1992) that does not require any bias voltage. Sufficiently high currents require high frequencies and thus fast tunneling rates and relatively high conductances where co-tunneling effects result in errors in electron manipulation and decreased accuracy of the standard. Modern designs utilize superconductivity and quantum dots, and the accuracy has been improved through years to achieve metrologically relevant values (Pekola et al., 2013; Wenz et al., 2019).

We have already mentioned the use of Coulomb blockade systems for precise thermometry (Meschke et al., 2016). A very natural application of SET is its use as a sensitive electrometer: the change of induced change just by a fraction of e may change the current by order of value. A fast and efficient electrometer design has been proposed in Schoelkopf et al. (1998). The small size of SET island permits its realization on a tip of a scanning probe (Yoo et al., 1997). With these devices, one can easily image single charges and peculiarities of electric field distribution in various 2D heterostructures.

Conclusion

We reviewed here Coulomb blockade: a universal phenomenon in the field of quantum transport, that is widely manifested in man-made nanostructures at low temperatures. The phenomenon permits a closed and easy description outlined here. We explain the concepts of charge quantization and charging energy, best illustrated by Single Electron Box. The transport in Coulomb blockade regime is governed by master equation involving the tunneling rates, Single Electron Transistor being the generic example. Single Electron pump and turnstile are prototypes for applications of the phenomenon. We extend the description to incorporate the essential quantum effects that provide electron co-tunneling and weak Coulomb blockade.

Abstract

Mobile electrons and phonons are carriers of heat in solids. The amplitude and the temperature dependence of thermal conductivity can be understood by quantifying the concentration of such carriers, their velocity, and the distance they travel between two successive collisions. In insulators, itinerant electrons are absent, and heat propagates thanks to phonons. The latter are scattered off each other at high temperature and by defects at lower temperatures. In metals, heat can be carried by electrons, which often dominate heat conductivity thanks to their larger velocity. In superconductors, electron carriers of heat vanish to a condensate and heat is carried by phonons and thermally excited quasi-particles, which may persist down to zero temperature when the superconducting gap has nodes. Heat can also be carried by magnetic excitations, such as magnons. Analysis of thermal transport is often complicated due to the fact that there are multiple carriers and various groups of scatterers and a quantitative account requires a disentanglement of different carriers and different scattering mechanisms.

Definition

Heat travels inside solids due to a property called thermal conductivity. The magnitude of thermal conductivity is specific to each element, alloy, or compound and is defined by the equation relating the heat flow to the thermal gradient produced by this flow:

$$J_q = -\kappa \nabla T \quad (1)$$

Here, J_q and ∇T are vectors representing respectively heat current density and temperature gradient. Thermal conductivity κ is, in general, a second-rank tensor. However, when heat flows along a high-symmetry axis, the temperature gradient created is parallel to the axis and the thermal conductivity along that particular axis may be treated as a scalar. In SI units, J_q is expressed in W m^{-2} and ∇T in K m^{-1} . The SI unit of thermal conductivity is therefore W(Km)^{-1} .

Eq. (1) is reminiscent of Ohm's law defining the electrical conductivity as the quantity relating the electric field to current density $J = -\sigma \nabla V$. Indeed, there are a number of analogies between the two transport properties. There is a big difference however: to conduct electric charge, a solid should host itinerant electrons. Otherwise, it would qualify as an (electric) insulator. In the world of heat conduction, such a sharp distinction between conductors and insulators does not exist. The fundamental reason behind this resides in the existence of phonons, which can carry heat even in the absence of any electronic heat conductivity.

Thermal conductivity and thermal diffusivity

Eq. (1) is relevant in the case of thermal equilibrium. In general, the exchange of heat implies a variation of temperature with time. Conservation of energy implies

$$c \frac{\partial T}{\partial t} = -\nabla J_q \quad (2)$$

where c is the heat capacity per unit volume of the compound. Since the specific heat of various compounds is usually expressed as heat capacity per unit mass (or molar mass), it should be multiplied by the density (or the molar density) of the compound to yield the c used here. A finite J_q means that the balance of heat entering to and exiting out of a volume element is not zero and the energy surplus (or deficit) changes the local temperature.

The combination of Eqs. (1) and (2) yields the so-called equation of heat, also called the Fourier equation:

$$\frac{\partial T}{\partial t} = D \nabla^2 T \quad (3)$$

where $D = \kappa/c$ is called the thermal diffusivity. It has the dimensions of an area divided by time ($\text{m}^2 \text{s}^{-1}$ in SI units). Thermal diffusivity is thus thermal conductivity divided by specific heat.

Kinetic theory of heat carriers

Electrons and phonons are the principal carriers of heat in a solid. Phonons are the elementary excitations of a vibrating crystal. In terms of solid-state physics, it is a particle with a definite energy and wave vector. Electrons here mean itinerant electrons capable of moving from one atom to the other. In order to grasp the basic differences between these two types of carriers, it is instructive to focus on a formula derived from the kinetic theory of gases. In this picture, the thermal conductivity is expressed as

$$\kappa = 1/3 c v l \quad (4)$$

where c is the specific heat per volume, v is the average velocity of the particles composing the gas, and l is the mean free path.

Phonons are bosonic quasiparticles with a specific heat displaying a T^3 temperature dependence at low temperature and then saturating to a constant value at temperatures of the order of the Debye temperature, Θ_D . The relevant velocity is the speed of sound (of the order of several kms^{-1} in a solid) and does not change much with temperature. Finally, the mean free path of phonons is limited by whatever impedes their free propagation in a crystal. At sufficiently low temperatures, nothing can scatter extended phonons of long wavelength. In this so-called “ballistic” regime, the mean free path of the phonon becomes comparable to the sample’s dimensions.

Electrons are fermions. Their specific heat is a linear function of temperature in ordinary temperatures, which remain much smaller than the Fermi temperature of most metals. The relevant velocity for them is the Fermi velocity (of the order of several hundreds of kms^{-1} in common metals). Finally, even in the cleanest samples and at low temperatures, their mean free path seldom exceeds a micrometer.

Thermal transport in insulating crystals

The case of insulators is simpler as there are no electrons to conduct or to scatter, and their thermal conductivity reflects the capacity of the lattice alone to conduct heat.

The Debye temperature sets the most important energy scale in this context, Θ_D . The thermal conductivity of an insulator peaks at a temperature, which is a fraction (often one-tenth) of Θ_D . This maximum marks the border between the two regimes: while at higher temperatures it is a phonon-phonon scattering which determines the phonon mean free path, l_{ph} , at lower temperatures, collision with defects becomes the predominant limit on l_{ph} . These two regimes are considered here separately:

1. *Low temperature (below $T_{\text{peak}} \sim 0.1 \Theta_D$)*. At this temperature range, the T^3 specific heat dominates the temperature dependence of thermal conductivity since l_{ph} displays a weak temperature dependence. With increasing temperature, l_{ph} decreases from the maximum attained in the $T = 0$ limit. Its temperature dependence is governed by the presence of defects in the crystal which scatter phonons in various ways. The cross section of a phonon with a specific scattering center (such as a point defect, a line defect, a planar defect, or a dislocation) is a function of the phonon wavelength λ_{ph} . As the temperature rises, the dominant wavelength in the phonon population increases ($\lambda_{\text{ph}} \propto k_B T$). Therefore, the relative importance of different scattering mechanisms is shifted with the change in temperature.
2. *High temperature (above $T_{\text{peak}} \sim 0.1 \Theta_D$)*. The maximum is related to the inflection in the temperature dependence of C_{ph} and l_{ph} . It marks the beginning of the predominance of the phonon-phonon scattering, which leads to a sharper decrease in l_{ph} . This is a consequence of the rise in the phonon population with increasing temperature. On the other hand, the specific heat increases less rapidly and eventually saturates to a constant value. Therefore, the temperature dependence of κ is governed by $l_{\text{ph}}(T)$. The expected temperature dependence of the latter is T^{-1} . The minimum thermal conductivity at high temperature is imposed by the lattice spacing. Indeed, l_{ph} cannot become significantly lower than the latter.

The case of glasses

In amorphous solids, the mean free path of the phonon, even at low temperatures, does not exceed a few lattice constants. Therefore, the magnitude of thermal conductivity is drastically reduced. A generic feature of glasses is the absence of a maximum in the temperature dependence of thermal conductivity. Since l_{ph} presents a weak temperature dependence, the overall behavior is governed by the variation of the specific heat. The difference of conductivities between a glass and a crystal is largely reduced at high temperatures, because of the short l_{ph} for traveling phonons in both cases. In the intermediate temperature range, the peak is often replaced with a plateau (Fig. 1).

Fig. 1 Thermal conductivity of insulating and metallic solids.

Thermal conductivity of metals and the Wiedemann-Franz law

In metals, heat is carried both by phonons and electrons. Lattice conductivity in metals suffers from the presence of electrons as additional scattering centers. In the peak region of thermal conductivity (around $0.1 \Theta_D$), clean insulators can surpass clean metals as the best thermal conductors. In other words, the additional electronic thermal conductivity cannot compensate the loss in lattice thermal conductivity. The latter is proportional to the strength of electron-phonon coupling and introduces a T -square term to the temperature dependence of the phonon thermal conductivity.

In most cases, the predominant contribution to heat transport in a metal is of electronic origin. The application of Eq. (2) to electrons yields:

$$\kappa_{el} = 1/3 C_{el} v_F l_{el} = 1/3 C_{el} v_F^2 \tau \quad (5)$$

where τ is the scattering time. This equation has a parenthood with the classical expression for electric conductivity:

$$\sigma = \frac{ne^2 \tau}{m} \quad (6)$$

with e and m representing the charge and the mass of electron, and n the carrier density. In both expressions, the conductivity is proportional to the scattering time. Thus, the ratio of the two conductivities is expected to be independent of scattering. Divided by temperature, this ratio yields the Lorentz number: $L = \kappa_{el}/\sigma T$. The Wiedemann-Franz law which establishes an intimate relationship between thermal conductivity and electric conductivity of a given metal, states that the Lorentz number is equal to a universal constant:

$$\frac{\kappa_{el}}{\sigma T} = \frac{\pi^2}{3} \left(\frac{k_B}{e} \right)^2 = L_0 \quad (7)$$

where k_B is the Boltzmann constant and L_0 is the Sommerfeld number. Wiedemann and Franz formulated their empirical law in 1853 after measuring the conductivities of various metals at room temperature. The quantum theory of metals gave a solid foundation to this law which is expected to hold in the $T = 0$ limit irrespective of almost any particularity of any known metal. The fundamental reason behind its universality is easy to grasp. Whatever impedes the transport of charge by electrons would also affect the transport of entropy by them. The ratio of the two conductivities, therefore, does not depend on the specific electronic properties of the metal.

The argument remains rigorously valid in the absence of inelastic collisions, that is, scattering events which do not imply a transfer of energy during the scattering. Such events occur at finite temperatures when electrons are scattered by phonons and disturb the transport of heat more efficiently. Indeed, such a collision may lead to a partial loss of the electron's energy (i.e., heat) without affecting its momentum producing a thermal resistance with no counterpart in the charge channel. At high temperatures, however, the loss of energy during inelastic collisions becomes negligible compared to the thermal energy, and the validity of the Wiedemann-Franz law is more or less restored (see Fig. 2).

Superconductivity and heat transport

Many metals become superconductors below a critical temperature, T_c . The transition has drastic consequences on heat transport both by electrons and by phonons. At the onset of superconductivity, a gap opens up in the energy spectrum of the electronic spectrum and individual electrons end up in a superconducting condensate. This condensate lacks any degree of freedom in order to

Fig. 2 The temperature dependence of the Lorentz number in a common metal (aluminum).

qualify as a carrier of entropy. Therefore, in the superconducting state, only the “normal fluid,” that is, electronic excitations which happen to exist due to their thermal energy at finite temperature, can carry heat. The number of such excitations decreases exponentially with temperature and at sufficiently low temperature, they cease to play any significant role in thermal transport.

Phonon heat transport is also affected by the superconducting transition. At the onset of superconductivity in many metals, electrons are a principal source of scattering for phonons. When this is the case, the condensation of electrons leads to a sharp enhancement in the phonon mean free path and the phonon thermal conductivity. At very low temperatures, an ordinary superconductor conducts heat in a manner analogous to an insulator.

The other consequences of the superconducting transition on the thermal conductivity of electrons and phonons generate a wide variety of behaviors in real superconductors. If the electrons are the dominant heat carriers at the onset of superconductivity, then the superconducting transition is accompanied by a rapid decrease in the thermal conductivity of the system. On the other hand, if for any reason (a low carrier density, a low mean-free path, a high critical temperature, etc.) the lattice contribution happens to be significant in the normal state, the thermal conductivity can increase below T_c reflecting the enhancement of l_{ph} . The superconductor should be clean enough for this to happen, otherwise the impurity scattering of phonons is such that the disappearance of electrons would not present any significant change in phonon scattering. Thus, according to the numerous relevant parameters of each case, the superconducting transition can lead to a reduction, to an enhancement, or to no change in the thermal conductivity of the system.

The picture of heat transport in superconductors in this article has been somewhat modified by the results of the last two decades of research on unconventional superconductors. In high- T_c cuprates, the entry of the system into the superconducting state is accompanied with an upturn in thermal conductivity. It is now generally believed that part of this enhancement is due to an increase in the electronic component of thermal conductivity. While there is still no microscopic understanding of what happens, this extraordinary situation is interpreted as a signature of strong electron-electron scattering present in the normal state of the cuprates. In other words, the suppression of electrons leads to a lower number of heat carriers with a longer mean-free path in such a way that the overall result is a significant enhancement of thermal conductivity. A second feature of interest is the complex structure of the superconducting gap in unconventional superconductors. Since their gap is anisotropic with a magnitude which becomes zero along definite orientations, low-energy electronic excitations can survive down to $T = 0$. The electronic thermal conductivity is not expected to be an exponentially decreasing function of temperature. This has been confirmed by experiments probing heat transport by these “nodal” quasiparticles.

Magnetic excitations as heat carriers

In a magnetically ordered solid, a new type of heat carriers appear. The elementary excitations of a magnetic lattice are called spin waves or magnons and can transport heat in a manner analogous to phonons. Most of the considerations regarding phonons are relevant for magnon heat transport with Curie or Néel temperature replacing the Debye temperature as the relevant energy scale. A quantitative isolation of the magnon contribution to heat transport is, however, a difficult experimental task as the deconvolution of various terms in their presence is far from obvious.

Entropy carriers associated with spin degrees of freedom are also expected in metals close to a magnetic stability. Such excitations, often called spin fluctuations or paramagnons, are reported to produce a substantial enhancement of thermal conductivity in a number of exotic metals.

Thermal magnetoresistivity and the Righi-Leduc effect

A magnetic field has no direct effect on heat transport by phonons. Electronic thermal conductivity, on the other hand, is affected by a magnetic field in a manner analogous to the electric conductivity. Usually, it is diminished as the magnetic field disfavors transport by charged particles.

In type II superconductors, a magnetic field penetrates the solid in the shape of mesoscopic filaments called vortices. These superconducting vortices constitute a new type of scattering centers for heat carriers. The contribution of their own movement to heat transport is often negligible.

In the presence of a magnetic field, the electronic thermal conductivity tensor presents a nondiagonal term, κ_{xy} . The trajectory of charged carriers is skewed under the influence of the Lorentz force (or magnetically aligned scattering centers). This creates a transverse heat current, which is balanced by a transverse thermal gradient. This is the Righi-Leduc effect, sometimes dubbed the thermal Hall effect in analogy to the famous electric one.

Measuring thermal conductivity

Experimental methods to determine thermal conductivity fall into two broad groups. Steady state or “static” methods study a sample time-independent temperature profile and measure κ using Eq. (1). In contrast, non-steady-state or “dynamic” methods work with a time-dependent temperature. They often yield a quantity akin to thermal diffusivity.

Measuring the thermal conductivity of a solid implies a reliable determination of the temperature gradient produced by a heat current, and the quality of an experimental setup depends on its ability to yield accurate values of these two quantities. This proves to be more difficult than the analogous case of electrical conductivity since charge can only travel through conductors but heat can be transmitted by conductors, insulators, and even vacuum.

Abstract

This article summarizes the basic approaches historically adopted for describing transport processes and, specifically, mass transport: elementary kinetic theory, Einstein's theory of Brownian motion, Langevin stochastic equation and Fokker-Planck probabilistic approach.

Key points

- Transport by an applied gradient, Brownian motion, Langevin approach, Fokker-Planck approach.

Introduction

Transport processes concern a wide range of phenomena in hydrodynamics, thermodynamics, physical-chemistry, electric conduction, magnetohydrodynamics, etc. They typically occur in physical systems (gases, liquids or solids) made of many particles (atoms or molecules) in the presence of inhomogeneities. Such a situation can result from non-equilibrium conditions (e.g., the presence of a macroscopic gradient of density, velocity and temperature), or simply from fluctuations around an equilibrium state (Chandler, 1987; Livi and Politi, 2017).

The kinetic theory of transport phenomena provides a unified description of these apparently unlike situations. It is based on the assumption that even in non-equilibrium conditions gradients are small enough to guarantee that local equilibrium conditions still hold. In particular, the kinetic approach describes the natural tendency of the particles to transmit their properties from one region to another of the fluid by colliding with the other particles and eventually establishing global or local equilibrium conditions.

The main success of the kinetic theory is the identification of the basic mechanism underlying all the above-mentioned processes: the transport of a microscopic quantity (e.g., the mass, momentum or energy of a particle) over a distance equal to the mean free path $\bar{\ell}$ of the particles, i.e. the average free displacement of a particle after a collisions with another particle. By this definition, it is implicitly assumed that the system is a fluid, where each particle is supposed to interact with each other by collisions and propagate freely between successive collisions. Simple considerations yield the following definition

$$\bar{\ell} = \frac{1}{\sqrt{2} \sigma n}, \quad (1)$$

where n is the volumetric density of particles, which depends on the thermodynamic conditions of the system, and σ is the total cross-section of collisions between particles (e.g., for the ideal case of spheric particles of radius R , $\sigma = 4\pi R^2$). For instance, in a gas at room temperature and pressure $\bar{\ell}$ is typically

$\mathcal{O}(10^{-5})$ cm, three orders of magnitude larger than the typical size of a particle, $\mathcal{O}(10^{-8})$ cm. It is worth stressing that reference is made to the simple case of a homogeneous isotropic system, where $\bar{\ell}$ is the same at any point and in any direction in space.

In the following section the general case of non-equilibrium conditions are analyzed and the definitions of transport coefficients are provided. In the section “Brownian motion” the process of mass transport due to fluctuations close to equilibrium is described, by relying upon the basic example of Brownian motion.

[☆]Change History: July 2022. R Livi updated the chapter.

Transport in the presence of a gradient

Without prejudice of generality a system is considered where a uniform gradient of the quantity $A(\vec{x})$ is established along the z -axis, and $A(x, y, z) = A(x', y', z) = A(z)$ for any x, x', y and y' . In particular, it is assumed that $A(z)$ is a microscopic quantity, which slowly varies at constant rate along the coordinate z of an arbitrary cartesian reference frame. Consider also a unit surface S_1 located at height z and perpendicular to the z -axis. Moving from the surface S_1 a particle will run a distance $\pm \bar{\ell}$ moving either upward or downward along the z axis, respectively. Assuming that local equilibrium is established by collisions, the particle variable will change its original value $A(z)$ into $A(z \pm \bar{\ell})$. The net transport of the quantity $A(z)$ through S_1 amounts to the number of crossings of S_1 from each side in the unit time. Consistently with the assumption of local equilibrium, the same average velocity $\bar{v}$ is attributed to all particles crossing S_1 . Isotropy and homogeneity of the system imply also that “on average” $\frac{1}{3}$ of the particles move along the z -axis, half of them upward and half down-ward. Accordingly, S_1 is crossed along z in the unit time interval by $\frac{1}{6} n \bar{v}$ particles in each direction. The net amount of $A(z)$ transported through S_1 in the unit time is given by

$$\Phi(A) = \frac{1}{6} n \bar{v} [A(z - \bar{\ell}) - A(z + \bar{\ell})] \quad (2)$$

Since $\bar{\ell}$ is very small compared with the macroscopic length of the fluid, one can use the approximation $A(z \pm \bar{\ell}) \simeq A(z) \pm \bar{\ell} \frac{\partial A}{\partial z}$ and rewrite Eq. (2) as

$$\Phi(A) = -\frac{1}{3} n \bar{v} \bar{\ell} \frac{\partial A}{\partial z} \quad (3)$$

The minus sign in front of the r.h.s. of this equation indicates that A is transported in the direction opposite to the orientation of the gradient. This calculation can be performed more carefully by introducing explicitly the Maxwell distribution function of particle velocities at equilibrium (e.g., see (Livi and Politi, 2017)). Nonetheless, one recovers the same result.

The simplest case is the presence of a density gradient along the z -axis, i.e. $A(z) = n(z)$. It induces a mutual transport of particles, which diffuse through the system and

$$\Phi(n) = -\frac{1}{3} n \bar{v} \bar{\ell} \frac{\partial n}{\partial z} = D \frac{\partial n}{\partial z} \quad (4)$$

where the quantity $D = \frac{1}{3} n \bar{v} \bar{\ell}$ defines the diffusion coefficient of particles inside the fluid.

This definition can be easily extended to the case of a mixture of two different species of particles, labeled by the indices (1) and (2), which diffuse into each other. One can define the mutual diffusion coefficient

$$D_{1,2} = \frac{n_1 \bar{v}_1 \bar{\ell}_1 + n_2 \bar{v}_2 \bar{\ell}_2}{3(n_1 + n_2)} \quad (5)$$

The other cases of physical interest correspond to the situations where a gradient of velocity or temperature are present. In the former case, it is assumed that the fluid flows with constant macroscopic velocity $v(z)$ parallel to the (x, y) plane. In such a situation there is a net transport of kinetic momentum $mv(z)$ (m is the mass of a particle), yielding a strain stress $\Phi(mv(z))$ between the fluid layers laying on the (x, y) plane:

$$\Phi(mv(z)) = -\frac{1}{3} n m \bar{v} \bar{\ell} \frac{\partial v(z)}{\partial z} = \eta \frac{\partial v(z)}{\partial z} \quad (6)$$

where the quantity $\eta = \frac{1}{3} n m \bar{v} \bar{\ell}$ defines the viscosity of the fluid. By substituting Eq. (1) into the previous expression, one finds $\eta = \frac{m \bar{v}}{3\sqrt{2}\sigma}$. This implies that the viscosity of an ideal fluid is independent of its density n , that is of the pressure. This counterintuitive conclusion was first derived by J.C. Maxwell and its experimental verification sensibly contributed to establish in the scientific community a strong consensus on the “atomistic” approach of kinetic theory (Brush, 1976). It is worth stressing that such a conclusion does not hold when dealing with very dense fluids.

It remains to consider the case when $A(z)$ is the average kinetic energy of particles $\bar{\epsilon}(z)$. At equilibrium, the energy equipartition condition yields the relation $n \bar{\epsilon}(z) = \rho C_V T(z)$, where $\rho = m n$ is the mass density of particles, C_V is the specific heat at constant volume and $T(z)$ is the temperature at height z . The net flux of kinetic energy $\Phi(\bar{\epsilon})$ can be read as the heat transported through the fluid along the z -axis:

$$\Phi(\bar{\epsilon}) = -\frac{1}{3} \rho C_V \bar{v} \bar{\ell} \frac{\partial T(z)}{\partial z} = \kappa \frac{\partial T(z)}{\partial z} \quad (7)$$

where the quantity $\kappa = \frac{1}{3} \rho C_V \bar{v} \bar{\ell} = \frac{m C_V \bar{v}}{3\sqrt{2}\sigma}$ defines the heat conductivity. Also κ is found to be independent of n .

One can conclude that the transport coefficients, i.e. the diffusion constant D , the viscosity η and the heat conductivity κ , are closely related to each other and depend on a few basic properties of the particles, like their mass m , their average velocity $\bar{v}$ and their mean-free-path $\bar{\ell}$. By comparing Eqs. (6) and (7) one finds the remarkable relation

$$\frac{\kappa}{\eta} = \alpha C_V \quad (8)$$

According to the results herein reported the value of the proportionality constant is $\alpha = 1$. In real systems this constant takes different values, which depend on specific features of particles interaction (e.g., $\alpha = \frac{5}{2}$ for realistic models of monoatomic gases (Livi and Politi, 2017)). The conceptual relevance of this relation is that it concerns quantities that originate from quite different conditions of matter. In fact, on the left hand side is the ratio of two transport coefficients associated with macroscopic

non-equilibrium conditions, while on the right hand side is a typically equilibrium quantity, the specific heat at constant volume. After what has been discussed in this section, this observation is far from mysterious: by assuming that even in the presence of a macroscopic gradient of physical quantities equilibrium conditions set in locally, the kinetic theory provides a unified theoretical approach for transport and equilibrium observables.

Brownian motion

The basic example of transport properties emerging from fluctuations close to equilibrium is Brownian motion (for a general overview on this topic see (Nelson, 1976)). This phenomenon had been observed by R. Brown in 1828: small pollen particles in solution with a liquid exhibited an erratic motion, whose irregularity increased with decreasing particle size (typically, 10^{-3} cm). The long scientific debate about the origin of Brownian motion lasted over almost one century and raised strong objections to the atomistic approach of the kinetic theory (see the section “Introduction”). In particular, the motion of the pollen particles could not be apparently consistent with an explanation based on collisions with the molecules of the liquid, subject to thermal fluctuations. In fact, pollen particles have exceedingly larger mass and size with respect to molecules. An easy calculation, based on orders of magnitude, yields the conclusion that the amount of velocity acquired by a pollen particle in a collision with a molecule is typically 10^{-6} m/s, so that the corresponding instantaneous displacement could not be practically observed, “a fortiori” with the optical devices available to Mr. R. Brown in 1828. The kinetic approach implies also that the number of collisions per second of the Brownian particle with liquid molecules is gigantic and random. Thermal equilibrium conditions and the isotropy of the liquid make equally probable the sign of the small velocity variations of the pollen particle. On observable time scales the effect of the very many collisions should average to zero and the pollen particle should not acquire any net displacement from its initial position in the fluid. This way of reasoning is actually wrong, as Albert Einstein argued in his theory of Brownian motion (Einstein, 1956). Einstein’s methodological approach, based on the combination of simple models with basic physical principles, was very effective: he first assumed that the Brownian macroscopic particles should be considered as “big mass molecules”, so that the systems composed by the Brownian particles and the solvent, where they are suspended, can be considered a mixture of two fluids at thermal equilibrium. This implies the validity of Van’t Hoff law

$$P(\vec{x}) = k_B T n(\vec{x}) \quad (9)$$

where P is the osmotic pressure between the fluids, T is the equilibrium temperature of the solution, n in the volumetric density of Brownian particles (the “solute” of the binary mixture) and k_B is the Boltzmann constant ($k_B = 1.380658 \times 10^{-23}$ J K $^{-1}$). According to the classical kinetic theory one should not be allowed to write an equation of state like (9) for a collection of the macroscopic Brownian particles. They should be better described by the laws of dynamics, rather than by those of thermodynamics. Einstein’s opposite point of view can be justified by considering that, despite their macroscopic dimension, the Brownian particles are not subject to standard macroscopic forces: they experience microscopic forces originated by thermal fluctuations of the fluid molecules and in this sense they can be assimilated in any respect to solute particles. The macroscopic nature of the Brownian particles should be recovered in the time scales associated with the collision and dissipation processes inside the fluid. Einstein guessed that Brownian motion looks random on a much larger time scale than the one needed for dissipating the energy acquired by Brownian particles through collisions with molecules. In practice, this amounts to assume that the dissipation mechanism should be described by the macroscopic Stokes’ law

$$F = m \frac{dv}{dt} = -6\pi\eta Rv \quad (10)$$

where F is the friction force proportional to the velocity v of the Brownian particle of radius R and η is the viscosity of the solvent. Accordingly, the energy dissipation process of Brownian particles has to occur on the time scale

$$t_d = \frac{m}{6\pi\eta R} \quad (11)$$

For $R \simeq 10^{-4}$ cm and for a standard solvent (e.g., water) one has $t_d = \mathcal{O}(10^{-7})$ sec.

On a time scale much larger than t_d the Brownian particles are expected to exhibit a diffusive motion, as a consequence of the many random collisions with the solvent molecules. On the other hand, the kinetic theory associates diffusion with transport of matter in the presence of a density gradient (see section “Introduction”). Einstein then assumed that some ideal external force should be responsible of creating such a gradient along an arbitrary direction (e.g., x) yielding a flux of Brownian particles

$$J_B = D\nabla n \quad (12)$$

At a microscopic level the flux of Brownian particles J_B is defined as the product of their velocity v times their density n . For $t \gg t_d$, the velocity v is given by Eq. (10) and one can also write

$$J_B = \frac{Fn}{6\pi\eta R} \quad (13)$$

The numerator on the right hand side of this equation is the definition of the pressure gradient, which, according to Van’t Hoff law (9), is proportional to the density gradient. In formulae

$$Fn = \nabla P = k_B T \nabla n \quad (14)$$

By substituting into Eq. (14) and comparing with Eq. (12) one obtains the remarkable relation

$$D = \frac{k_B T}{6\pi\eta R} \quad (15)$$

J. Perrin showed that this formula provides very good quantitative agreement with experimental data (Perrin, 1948).

In summary, Einstein's approach derives from the assumption that for $t < t_d$ it still makes sense attributing a velocity to the Brownian particle (see Eq. (10)), while for $t > t_d$ the particle is assumed to diffuse, as if it would be in the presence of an ideal density gradient (Eq. 12). It is worth stressing that the last hypothesis is purely phenomenological, since direct inspection of the movement of Brownian particles revealed its diffusive nature. Einstein's theory of Brownian motion is based on the matching between different dynamical regimes.

The Langevin approach

A mechanical approach taking explicitly into account both dynamical regimes was later proposed by P. Langevin (Livi and Politi, 2017; Van Kampen, 1985). For the first time deterministic and stochastic forces were introduced into the same equation. The deterministic component is the friction term $-\gamma\mathbf{v}$, acting on the Brownian particle: γ is the friction coefficient, which amounts to $\gamma = 6\pi\eta R$ in the Stokes regime and $\mathbf{v}$ is the three-dimensional velocity vector of the Brownian particles, whose components are denoted by v_i , $i = 1, 2, 3$. The stochastic component associated with the effect of collisions with the solvent molecules is a random, time-dependent force vector $\xi(t)$, whose components are analogously denoted by ξ_i , $i = 1, 2, 3$. Symmetry arguments indicate that each one of these components can be assumed to be independent, isotropic, uncorrelated in time (at least for $t > t_d$) and gaussian, since it results from the combination of a very large number of collisions, which can be approximately considered as independent events. Accordingly, the average of the stochastic force is null and its time-correlation function can be approximated by a Dirac delta for $t > t_d$. In formulae:

$$\langle \xi_i(t) \rangle = 0 \quad (16)$$

$$\langle \xi_i(t) \xi_j(t') \rangle = \Gamma \delta_{ij} \delta(t - t') \quad (17)$$

where the brackets $\langle \rangle$ indicate the statistical average, Γ is a suitable dimensional constant and δ_{ij} is a Kronecker delta. Langevin equation is a Newton equation containing the stochastic force vector ξ . For each component of the three-dimensional velocity vector it reads

$$m \frac{dv_i}{dt} = -\gamma v_i + \xi_i(t) \quad (18)$$

This equation can be formally integrated, yielding the solution

$$v_i(t) = \exp\left(-\frac{\gamma}{m}t\right) \left[v_{0i} + \int_0^t d\tau \frac{1}{m} \exp\left(\frac{\gamma}{m}\tau\right) \xi_i(\tau) \right] \quad (19)$$

where v_{0i} is the i -th component of the initial velocity. Accordingly, $v_i(t)$ is a stochastic solution which assumes properties similar to $\xi(t)$ (see Eq. (17)), namely

$$\langle v_i(t) \rangle = v_{0i} \exp\left(-\frac{\gamma}{m}t\right) \quad (20)$$

and

$$\langle v_i^2(t) \rangle = \exp\left(-\frac{2\gamma}{m}t\right) \left[v_{0i}^2 + \int_0^t d\tau \frac{1}{m^2} \exp\left(\frac{2\gamma}{m}\tau\right) \Gamma \right] \quad (21)$$

$$= \frac{\Gamma}{2m\gamma} \left[1 - \exp\left(-\frac{2\gamma}{m}t\right) \right] + v_{0i}^2 \exp\left(-\frac{2\gamma}{m}t\right) \quad (22)$$

As time t grows the average velocity vanishes exponentially with the rate $\frac{m}{\gamma}$, while the average squared velocity approaches the value

$$\lim_{t \rightarrow \infty} \langle v_i^2(t) \rangle = \frac{\Gamma}{2m\gamma} \quad (23)$$

In order to bridge this purely mechanical approach with Einstein's theory, a relation with thermodynamics has to be established. This is naturally obtained by attributing a thermal origin to the fluctuations of the stochastic force. In particular, if one assumes that the Brownian particles and the solvent are at thermal equilibrium with temperature T , the energy equipartition principle establishes that the average kinetic energy per degree of freedom in the limit of very large times is proportional to the temperature:

$$\lim_{t \rightarrow \infty} \left\langle \frac{1}{2} m v_i^2(t) \right\rangle = \frac{1}{2} k_B T \quad (24)$$

By comparison with Eq. (23) one obtains the remarkable relation

$$\Gamma = 2\gamma k_B T \quad (25)$$

where the amplitude of velocity fluctuations is found to depend on the friction coefficient of the fluid, thus yielding the basic example of a fluctuation-dissipation relation (for a general approach to fluctuation-dissipation theory see (Livi and Politi, 2017; Kubo et al., 1985)).

On the other hand, this relation cannot be directly tested by experimental observations, i.e. records of the erratic trajectories of Brownian particles sampled at time intervals much larger than t_d . The very predictive content of the Langevin equation can be extracted by computing the average displacement vector $\mathbf{r}$, whose components are related to those of $\mathbf{v}$ by the straightforward relation $r_i(t) = \int_0^t d\tau v_i(\tau)$, $i = 1, 2, 3$. The information of interest is contained in the expression of the squared average displacement $\langle r_i^2(t) \rangle$. Simple calculations yield the result

$$\langle r_i^2(t) \rangle = v_{0i}^2 t^2, \quad t < \frac{m}{\gamma} \quad (26)$$

$$\langle r_i^2(t) \rangle = \frac{2k_B T}{\gamma} t, \quad t > \frac{m}{\gamma} \quad (27)$$

It is important to observe that this mechanical approach is able to account at the same time for the “ballistic” regime, expected for times smaller than the relaxation time $t_d = \frac{m}{\gamma}$, and also for the asymptotic diffusive regime. The diffusion constant is expressed by the relation

$$D = \frac{k_B T}{\gamma} \quad (28)$$

which is found to be equivalent to (15) in the Stokes friction regime, where $\gamma = 6\pi\eta R$.

The Fokker-Planck approach

The statistical content of the Langevin approach emerges explicitly from the properties attributed to the random force in Eq. (17). The statistical average $\langle \rangle$ can be interpreted as the result of the average over many different trajectories of the Brownian particle obtained by different realizations of the stochastic force components ξ_i in Eq. (18). By taking inspiration from Boltzmann kinetic theory (see (Huang, 1987)) one can get rid of mechanical trajectories and describe from the very beginning the evolution of Brownian particles by a suitable distribution function $f(\mathbf{x}, t)$: $f(\mathbf{x}, t)d\mathbf{x}$ represents the probability of finding the Brownian particle at a position in between $\mathbf{x}$ and $\mathbf{x} + d\mathbf{x}$ at time t . One can introduce the transition rate $W(\mathbf{x}', \mathbf{x})$, such that $W(\mathbf{x}', \mathbf{x})d\mathbf{x}'\Delta t$ represents the probability that in the interval of time Δt the Brownian particle “jumps” from the neighborhood of $\mathbf{x}$ to $\mathbf{x}'$. In this approach any reference to instantaneous collisions with the solvent molecules is lost and one has to assume that $\Delta t \gg t_d$. As proposed by Fokker and Planck, one can write the evolution equation for $f(\mathbf{x}, t)$ as a “Master Equation”, i.e. a balance equation where the variation in time of $f(\mathbf{x}, t)$ emerges as the result of two competing terms: a gain factor, due to jumps of particles from any position $\mathbf{x}'$ to $\mathbf{x}$, and a loss factor, due to jumps from $\mathbf{x}$ to any $\mathbf{x}'$. In formulae

$$\frac{\partial f(\mathbf{x}, t)}{\partial t} = \int_{-\infty}^{+\infty} d\mathbf{x}' [f(\mathbf{x}', t)W(\mathbf{x}, \mathbf{x}') - f(\mathbf{x}, t)W(\mathbf{x}', \mathbf{x})] \quad (29)$$

In this equation it has been implicitly assumed that volumes are preserved in position space by the Brownian process, in particular $d\mathbf{x}' = d\mathbf{x}$. On the other hand, large displacements of the Brownian particles are highly improbable and one can reasonably assume that the rate function $W(\mathbf{x}', \mathbf{x}) = W(\mathbf{x}'; \chi)$ is significantly different from zero only for very small values of $|\chi| = |\mathbf{x}' - \mathbf{x}|$. This allows to introduce a formal Taylor series expansion in Eq. (29) around $\chi = 0$. By considering only terms up to the second order one obtains the Fokker-Planck equation

$$\frac{\partial f(\mathbf{x}, t)}{\partial t} = -\nabla \cdot [\mu_1 f(\mathbf{x}, t)] + \frac{1}{2} \Delta [\mu_2 f(\mathbf{x}, t)] \quad (30)$$

where

$$\mu_1 = \int_{-\infty}^{+\infty} d\chi W(\mathbf{x}'; \chi) \chi = \left\langle \frac{\delta \mathbf{x}}{\delta t} \right\rangle = \langle \mathbf{v} \rangle \quad (31)$$

$$\mu_2 = \int_{-\infty}^{+\infty} d\chi W(\mathbf{x}'; \chi) |\chi|^2 = \left\langle \frac{|\delta \mathbf{x}|^2}{\delta t} \right\rangle \quad (32)$$

The first term on the r.h.s. of Eq. (30) represents the contribution of viscous friction, while the second term is the diffusive contribution. Notice that vector μ_1 and scalar μ_2 are both average quantities: the former amounts to the average speed of a Brownian particles, which in general results from the balance of external forces acting on the Brownian particle with the viscous friction force produced by the solvent; the latter amounts to the average squared displacement per unit time, which, in a homogeneous isotropic medium, corresponds to the definition of the diffusion constant D . Accordingly, in the absence of external forces the viscous term can be neglected and Eq. (30) reduces to the standard form of a macroscopic diffusion equation

$$\frac{\partial f(\mathbf{x}, t)}{\partial t} = D \Delta f(\mathbf{x}, t) \quad (33)$$

The solution of this equation is

$$f(\mathbf{x}, t) = \frac{1}{\sqrt{4\pi Dt}} \exp\left(-\frac{|\mathbf{x} - \mathbf{x}_0|^2}{4Dt}\right) D \Delta f(\mathbf{x}, t) \quad (34)$$

Here $\mathbf{x}_0$ is the initial position of the Brownian particle. The average squared displacement is given by the expression

$$\langle |\mathbf{x}|^2 \rangle = \int_{-\infty}^{+\infty} d\mathbf{x} |\mathbf{x}|^2 f(\mathbf{x}, t) = |\mathbf{x}_0|^2 + 6Dt \quad (35)$$

This statistical treatment of Brownian motion can be easily generalized in the presence of external forces acting on the Brownian particles. For the sake of simplicity the simple case of an elastic force acting $\mathbf{F} = -\lambda \mathbf{x}$, where λ is the elastic constant (Uhlenbeck and Ornstein, 1930), is illustrated. The mobility of Brownian particles is denoted as v (e.g., in the Stokes regime $v^{-1} = 6\pi\eta R$). The average viscous force is then given by $-\langle \mathbf{v} \rangle / v$ and it must be balanced by the elastic force, i.e. $\langle \mathbf{v} \rangle / v + \lambda \mathbf{x} = 0$. This relation implies

$$\mu_1 = -\lambda v \mathbf{x} \quad (36)$$

Since relation (35) still holds, one also obtains

$$\mu_2 = \langle |\mathbf{x}|^2 \rangle / t = 6D \quad (37)$$

where, without prejudice of generality, one can set $\mathbf{x}_0 = 0$. Eq. (30) then reduces to

$$\frac{\partial f(\mathbf{x}, t)}{\partial t} = \lambda v \nabla \cdot \mathbf{x} f(\mathbf{x}, t) + 3v k_B T \Delta f(\mathbf{x}, t) \quad (38)$$

where the generalized Einstein's relation $D = v k_B T$ has been used. The solution of (38) reads

$$f(\mathbf{x}, t) = \sqrt{\frac{\lambda}{2\pi k_B T (1 - e^{-2\lambda vt})}} \exp\left(-\frac{\lambda |\mathbf{x} - \mathbf{x}_0 e^{-\lambda vt}|^2}{2k_B T (1 - e^{-2\lambda vt})}\right) \quad (39)$$

One can easily obtain

$$\langle \mathbf{x} \rangle = \mathbf{x}_0 e^{-\lambda vt} \quad (40)$$

$$\langle |\mathbf{x}|^2 \rangle = |\mathbf{x}_0|^2 e^{-2\lambda vt} + \frac{k_B T}{\lambda} (1 - e^{-2\lambda vt}) \quad (41)$$

In the limit $t \rightarrow \infty$ these relations reduce to

$$\langle \mathbf{x} \rangle = 0 \quad (42)$$

$$\langle |\mathbf{x}|^2 \rangle = \frac{k_B T}{\lambda} \quad (43)$$

It can be concluded that asymptotically the distribution of Brownian particles subject to an elastic force is a gaussian centered around the origin (which has been chosen as the equilibrium position of the elastic force), with variance $\frac{k_B T}{\lambda}$.

Conclusion

This manuscript contains a pedagogical overview about the basic methods employed in physics for describing mass transport in fluids, according to a historical perspective. In fact, the approach of elementary kinetic theory is first reported to provide the reader a basic intuitive understanding of transport processes, where dynamical and statistical concepts were mixed together for the first time, in order to obtain a clear definition of the phenomenological coefficients associated with diffusive processes in fluids. The understanding of Brownian motion by Einstein's theory is then illustrated as a basic contribution pointing out the role of thermodynamic equilibrium in relation with transport processes. Further mathematical achievements by Langevin stochastic equation and Fokker-Planck probabilistic equation are finally reported. By the latter formalism a short account about the problem of diffusive particles subject to an external elastic force (the so-called Ornstein-Uhlenbeck problem) is also reported.

Abstract

When the polarity of a non-centrosymmetric polar structure can be reversed one normally finds a set of additional characteristic properties, altogether designated as ferroelectricity. We outline these properties and the systems in which they are materialized with some representative examples. In particular, we delineate the standard case in which ferroelectricity is associated with a phase transition—that is, to some sort of underlying instability—and emphasize another class of ferroelectricity that is beyond this paradigm. The former can be described within the Landau theory of phase transitions and its extensions and takes place in proper ferroelectrics (e.g., BaTiO₃, PbTiO₃, BiFeO₃ and HfO₂), improper ferroelectrics (e.g., hexagonal manganites such as YMnO₃) and multiferroics (e.g., orthorhombic manganites such as HoMnO₃ and TbMnO₃). The latter, however, is beyond the Landau framework and is found in 2D van der Waals materials for example.

Key points

- Definition of ferroelectricity (from physical measurements).
- Outline of applications.
- Ferroelectricity as a structural phase transition (within the Landau-theory paradigm):
 - equilibrium states
 - dynamics
 - domains, domain walls and ferroelectric textures
 - ferroelectricity in liquid crystals and incommensurate structures
 - proper ferroelectrics, improper ferroelectrics and multiferroics.
- Ferroelectricity beyond the Landau-theory paradigm.

Introduction

Ferroelectricity refers to a set of phenomena that takes place in materials with stable polar structures whose polarity can be reversed. These materials are called ferroelectrics. Ferroelectricity is useful for a number of technological applications, including information storage. Traditionally, ferroelectrics are defined as pyroelectrics whose natural electric polarization can be switched (see e.g., *Lines and Glass, 1977; Smolenskii, 1984*). However, ferroelectricity is also compatible with metallicity and magnetic order. This leads to the additional categories of ferroelectric metals and multiferroics.

In proper ferroelectrics, ferroelectricity implies a spontaneous symmetry breaking since there is always a reference non-polar structure that becomes (or would become) unstable with respect to polar distortions.¹ In many systems this happens by lowering the temperature. Such a loss of stability coincides with the transition temperature when the transition is continuous (or second order). These two points, however, are different when the transition is discontinuous (or first order). In this case, the transition point is above the undercooling limit of the non-polar state but below the overheating limit of polar one. Normally the difference between these points is small (e.g., a few degrees in the case of BaTiO₃) and the transition can be considered as weakly discontinuous.

The vicinity to such an instability explains not only the polarity reversal in these systems, but also their generic and multifaceted softness. The latter manifests through enhanced dielectric and piezoelectric responses, low-frequency optical vibration modes, and the appearance of ferroelectric textures such as domains and domain walls for example (that is, equivalent variants of the same ferroelectric phase and the spatial regions that separate them). In the so-called improper ferroelectrics, however, the instability is symmetry-wise different and the polar structure appears just as a by-product. Yet ferroelectrics of this type can also have interesting properties associated with the corresponding polarity, even if their inherent softness manifests differently. Furthermore, irrespective of any instability, the polarity reversal may be enabled by the weakness atomic bonding itself as in van der Waals systems, thereby defining a distinct class of genuinely different ferroelectric materials. In this article, we introduce these defining aspects of ferroelectricity in general terms.

Probing ferroelectricity

Historically, ferroelectricity has been discussed in dielectrics and defined from the electric polarization P (Lines and Glass, 1977; Smolenskii, 1984; Strukov and Levanyuk, 1998). In fact, the electric polarization P is one of the variables that formally describes the state of matter under a given set of physical conditions. Further, the equation of state (or constitutive equation) provides the relationship between these variables, which is useful in describing the properties of the corresponding system. In most ferroelectrics, the electric polarization can be associated to relatively small atomic displacements that render the corresponding structure polar² as illustrated in Fig. 1.

However, in traditional experiments such as the illustrated in Fig. 2, the quantity that is probed experimentally is the electric charge density instead. The so-called electric displacement D embodies such a charge density and is related to the electric polarization as $D = \epsilon_0 E + P$, where ϵ_0 is the vacuum permittivity and E the electric field.

In the setup illustrated in Fig. 2(a), the constitutive equation $P(E)$ of the capacitor's dielectric is determined from the charge Q of the reference capacitor that is obtained via the applied voltage V ($D = Q/A$ and $E = V/d$, where A is the area of the plates and d is the plate separation). This would give the static constitutive equation if the measurement frequency is low enough. In most dielectrics P depends linearly on E up to dielectric breakdown fields [Fig. 3(a)]. In ferroelectrics, however, the form of $P(E)$ is qualitatively different [Fig. 3(b)]. Specifically, it has a nonlinear character and eventually becomes multivalued for $E = 0$ in the ferroelectric phase. Consequently, the system displays (at least) two equivalent states in which there is a “spontaneous” polarization. Then, by applying an electric field in the direction opposite to the spontaneous polarization, this polarization can be reversed if the field is higher than the

Fig. 1 Illustration of simple atomic displacements changing the symmetry of the crystal from non-polar to polar, thereby giving rise to a spontaneous polarization. For the sake of concreteness, the depicted cells correspond to the cubic $\rightarrow$ tetragonal structures of ABO_3 perovskites such as BaTiO₃ (A in gray, B in blue and O in red).

¹The term “spontaneous symmetry breaking” is used to indicate the process in which a state becomes unstable and ends up in a less symmetric state by means of a symmetry-preserving agent such as temperature, hydrostatic pressure or chemical composition. For an illustration of this phenomenon based on a simple mechanical model see e.g., [Levanyuk, A.P., Burc M., I. and B. Okatan, M., 2020. Landau, Ginzburg, Devonshire and others. *Ferroelectrics*, 569(1), pp. 310–323].

²The crystallographic point group of a polar structure can be 1, 2, m , $mm2$, 4, $4mm$, 3, $3m$, 6, or $6mm$, where every operation symmetry leaves more than one point unmoved (so that at least one component of vector quantities is invariant).

Fig. 2 The dependence of the electric polarization on the electric field can be measured with alternating voltage by means of the capacitor setup illustrated in (a). On one hand, the charge Q of the reference empty capacitor is the same as the charge of the filled capacitor. On the other hand, the y -deflection is proportional to Q while the x -deflection is proportional to the voltage on the dielectric plate. Further, the electric displacement is $D = Q/A$ with A being the area of the capacitor's plates, so that this experiment provides $D(E)$. In ferroelectrics usually $\epsilon_0 E \ll P$ so that $D \sim P$. The change in the electric polarization, in its turn, can be measured with the setup illustrated in (b). In this case, one determines the transient currents obtained due to temperature changes (pyroelectric effect) or deformations (piezoelectric effect). The arrows indicate either heat flow or mechanical stress. The measured current then is $I = AdP/dt$.

Fig. 3 Electric polarization P as a function of the electric field E for (a) a linear dielectric with $\epsilon = 10$ and (b) the triglycine sulfate (TGS) measured at ambient temperature and frequency 0.1 Hz. The spontaneous polarization of this ferroelectric is $3.1 \times 10^{-2} \text{ C m}^{-2}$ and the coercive field is $E_c = 15 \text{ kV m}^{-1}$. From previous edition of the Encyclopedia of Condensed Matter Physics.

so-called “coercive field” [see Fig. 3(b)]. This was first observed in Rochelle salts more than 100 years ago and subsequently in other systems like potassium-dihydrogen phosphate (KDP). The oxide BaTiO_3 , however, was the first robust-enough material in which ferroelectricity was observed in the mid-1940s and perovskites of this type still represent a testbed for ferroelectricity.

Fig. 2(b) sketches another type of canonical experiment to probe the variations of P . In this case, the setup measures transient electric currents that appear due to either a variation in temperature of the ferroelectric (pyroelectric effect) or its deformation (piezoelectric effect). In these experiments the electrodes are short-circuited. In this way, the electric field that would appear due to the spontaneous electric polarization in the ferroelectric³ is compensated by free charges at the electrodes. This compensation is temporarily destroyed when the polarization changes due to the aforementioned perturbations and then restored via the transient currents. Thus, the measured current tracks the change in polarization and the direction of this current is linked to its orientation.

In order to have the pyroelectric effect, the structure of the system needs to be polar. Pyroelectric and piezoelectric effects, however, are not completely independent. The polarization may always change with the temperature as any characteristics of a crystal. This can happen in the absence of any deformation—i.e., in a completely clamped crystal—and also due to the thermal expansion in a free crystal. In the latter case the change in polarization can be seen as consisting of two parts: one directly associated with change in temperature, as if the crystal were clamped, and a second one due to the dependence of the polarization on the (temperature-induced) strains. The second part matches the polarization change obtained at fixed temperature when the same strains are produced by other means, and corresponds to the piezoelectric effect obtained via symmetry-preserving strains (as the thermal expansion do). However, there are also other strains that do change the symmetry of the crystal. These strains can be responsible for the piezoelectric effect even in non-polar yet non-centrosymmetric materials.

³In the hypothetical case of a free-standing ideal ferroelectric slab, homogeneously polarized, this field would be $-P/\epsilon_0$ due to the bound charges that appear at the boundaries (recall that $-\nabla \cdot P = \rho_{\text{bound}}$ where ρ_{bound} is the bound charge density). This field is the so-called depolarization field. It is opposite to the polarization and the energy associated to it represents an energy penalty that is avoided when the overall polarization is suppressed, which explains its name. In fact, to get a homogeneously polarized state as a result of phase transition with spontaneous symmetry breaking one has to eliminate this field. In theory, this is possible by means of the short-circuited ideal metallic electrodes. In practice, this field is reduced by the formation of domains—i.e., regions with opposite polarity (see below)—in most cases. The depolarizing field can also cause the diffusion of ions and the formation of charged defects.

Applications

The name “ferroelectrics” is due to the analogy between the aforementioned hysteretic behavior and that of ferromagnets. This property makes ferroelectrics similarly useful for memory and logic devices. This was proposed already in the 50s, although this type of ferroelectric devices was not suitable for commercialization due to material issues until the 90s (Auciello et al., 1998). At present new promising perspectives are discussed in this respect (Mikolajick et al., 2020; Mikolajick et al., 2021). Other applications of ferroelectrics are connected with their very large dielectric response: note the difference in scales of the P -axis in Fig. 3(a) and (b). In fact, if the electric field is low enough (in particular smaller than the coercive field), ferroelectrics behave as ordinary dielectrics but with very high dielectric constants $\varepsilon = 1 + \varepsilon_0^{-1} dP/dE$. This enables to obtain a high capacitance in a small volume, which is exploited in commercially available capacitors. Ferroelectric ceramics based on perovskite materials such as BaTiO_3 and $\text{Pb}(\text{Zr,Ti})\text{O}_3$ are commonly used in these capacitors (Lines and Glass, 1977). A high dielectric constant is also interesting for applications as gate insulators in field effect transistors. In addition, the spontaneous polarization itself can be used to retain the transistor's state in the absence of external bias in ferroelectric field-effect transistors. In this respect, HfO_2 is currently considered as a particularly promising material. This oxide was initially introduced as a replacement of SiO_2 since it is integrable into silicon technology and displays a dielectric constant 4–6 times larger. However, the subsequent discovery of ferroelectricity in this system enlarges considerably its potential applications (Dragoman et al., 2021; Khan et al., 2020; Mikolajick et al., 2020).

The strength of both the pyroelectric and the piezoelectric effects in ferroelectrics can be much higher than in non-ferroelectric pyroelectric and piezoelectric materials due to different reasons outlined below. These features are exploited in thermal detectors, transducers, actuators and resonators (Lines and Glass, 1977; Smolenskii, 1984). The $\text{Pb}(\text{Zr,Ti})\text{O}_3$ ceramic, in particular, has long been the most commonly used piezoelectric ceramic.

Ferroelectricity also yields specific optical properties such as second-harmonic generation that can be used to probe the properties of ferroelectric materials. Conversely, ferroelectric materials such as LiNbO_3 find applications thanks to these properties in nonlinear optics for example for laser frequency doubling. It becomes effective due to the so-called quasi-phase matching in a stable periodically polarized medium which can be realized in LiNbO_3 (Hum and Fejer, 2007). An interesting and highly non-trivial optical property of ferroelectrics and other non-centrosymmetric materials is the bulk photovoltaic effect, i.e., the generation of electric currents by light in absence of electric field and inhomogeneities (Sturman and Fridkin, 2021). Further, advances in microscopy enables to probe ferroelectricity at the atomic scale. This is particularly useful to study domains and domain walls, and thereby the local properties of ferroelectric materials that can be useful for device miniaturization. In fact, a number of ferroelectric materials can be grown with high quality by means of different deposition techniques and their ferroelectric properties can thus be engineered in heterostructures and superlattices.

Landau-Ginzburg-Devonshire framework

The electric polarization of traditional ferroelectrics has an emergent character in the sense that it can be associated to “spontaneous” changes in the structure of a reference, non-polar phase (see Fig. 1). These changes appear as a function of control parameters such as temperature or pressure in the absence of external electric field and involve relatively small atomic displacements. These displacements, however, change the symmetry of the material from non-polar to polar. This circumstance enables to describe ferroelectricity within the Landau theory of phase transitions, and thereby to describe a number of ferroelectric properties within a universal, material-independent framework (Strukov and Levanyuk, 1998). This was first put forward by Ginzburg, who identified the corresponding order parameter with the electric polarization P . A formally equivalent theory but with another background was proposed shortly after by Devonshire. Thus, when applied to ferroelectrics in this way, the Landau theory of phase transitions is called Landau-Ginzburg-Devonshire (LGD) theory.

Before illustrating the LGD theory, we first consider a conventional dielectric in the presence of an electric field E . Because of the long-range nature of the Coulomb interaction, the potential energy of the dielectric depends on the overall configuration of the system beyond the dielectric itself. Bearing this in mind, it is convenient to assume that the dielectric is sandwiched between metallic plates that are connected to a charge reservoir (e.g., ideally an infinite side capacitor). Thus, the potential energy per unit volume of the dielectric as a function of the electric polarization P becomes $U = \frac{1}{2\varepsilon_0\chi} P^2 - E \cdot P$,⁴ where χ is the electric susceptibility. The minimization of this energy with respect to P then gives the standard relationship $P = \varepsilon_0\chi E$ associated to Fig. 3(a). Note that, by using the potential energy to determine the polarization of equilibrium, we tacitly assume the classical limit for a system that is at zero temperature.

As we said before, the response of ferroelectrics is qualitatively different as it implies the hysteretic behavior illustrated in Fig. 3(b). This behavior, however, can be conveniently reproduced by generalizing the above potential energy to the LGD form⁵

⁴The first term in the expression $U = \frac{1}{2\varepsilon_0\chi} P^2 - E \cdot P$ is directly associated with the dielectric while the second comes from the total electrostatic energy $\int_1 \frac{\varepsilon_0}{2} E^2 dv + \int_2 \frac{\varepsilon_0}{2} E^2 dv$. Here the first integral is carried out over the volume of the dielectric while the second one refers to the side capacitor acting as a charge reservoir. When $P = 0$ in the dielectric, then the electrostatic energy reduces to $\int_2 \frac{\varepsilon_0}{2} E^2 dv = \frac{Q^2}{2C}$ (Q is the total charge in the reservoir and C its capacitance). When $P \neq 0$, however, the charge $q = PA$ is transferred to the dielectric and therefore the electrostatic energy of the reservoir becomes $\frac{(Q-q)^2}{2C}$. The change in the electrostatic energy is therefore $\frac{(Q-q)^2}{2C} - \frac{Q^2}{2C} = -\frac{qQ}{C} + \frac{q^2}{2C} \approx -\frac{qQ}{C}$. Here $\frac{Q}{C} = V$ is the voltage difference. Since $E = VA/v_1$ and $q = PA$ in the dielectric, then the total change in electrostatic energy in energy per unit volume becomes $-EP$.

⁵For the sake of simplicity, we consider the case of a uniaxial ferroelectric in which the z direction is taken along the spontaneous polarization (so that $P = P_z$). The generalization to a multiaxial ferroelectric, in which the spontaneous polarization can point along different directions, is straightforward.

$$U = \frac{a}{2}P^2 + \frac{b}{4}P^4 - EP \quad (1)$$

whose minimization requires

$$aP + bP^3 = E. \quad (2)$$

Compared to the previous case, Eq. (1) can be seen as an energy expansion up to the next order in P as required if the $\mathcal{O}(P^2)$ term is comparatively small. The coefficient b then needs to be $b > 0$ in order to bound the energy from below. This expansion might be necessary irrespective of any ferroelectricity (i.e., for a non-linear dielectric). The emergence of ferroelectricity, however, can be described in this way by further assuming that the a coefficient in Eq. (1) vanishes and eventually changes sign from positive to negative (see Fig. 4). For $E = 0$, in particular, the solution of Eq. (2) is

$$P = \begin{cases} 0 & \text{if } a > 0 \\ \pm\sqrt{-a/b} & \text{if } a < 0 \end{cases}. \quad (3)$$

Further, the hysteretic $P(E)$ behavior shown in Fig. 3(b) is then automatically obtained as explained in Fig. 4(b) and (c).

In reality, Ginzburg and Devonshire put forth this approach to treat ferroelectric phase transitions driven by temperature. In this case, however, the equilibrium state is determined, not by the minimum of the potential energy, but by the minimum of a (non-equilibrium) free energy—i.e., the Landau free energy—whose precise meaning will be discussed below. Ginzburg and Devonshire skipped this point and directly employed a postulated free energy as we employed Eq. (1) above to successfully explain many properties of ferroelectrics. The conceptual foundations of this approach and its fundamental difficulties were pointed out at a later time as we outline below. For Ginzburg and Devonshire's purposes, however, these difficulties had no practical importance.

Thus, the original LGD theory bases on a free energy analogous to Eq. (1) where the coefficient a is assumed to vary via the temperature as $a(T) = a_0(T - T_c)$.⁶ Accordingly, the electric polarization is found to increase gradually from zero in a continued fashion, describing a continuous (or second-order) paraelectric-ferroelectric transition. This is illustrated in Fig. 5(a).

Fig. 4 (a) LGD form of the potential energy for $E = 0$. (b) Electric polarization as a function of the electric field according to Eq. (2) for $a < 0$. The solid part of the curve corresponds to solutions that, depending on the sign of the electric field, are either global or local minima of the energy while the dashed part corresponds to maxima. For $E > 0$, for example, the points A, B, and C correspond to stable, metastable and unstable states respectively as indicated in (c).

Fig. 5 Spontaneous polarization (a) and dielectric constant (b) measured as a function of temperature in triglycine sulfate (TGS). From Strukov BA, and Levanyuk AP (1998) *Ferroelectric Phenomena in Crystals*. Berlin: Springer. p. 27.

⁶The control parameter is typically temperature, pressure or chemical composition and the coefficients of the Landau free energy are expanded in terms of these quantities as a power series, retaining the lowest-order terms only.

The dielectric susceptibility, in its turn, is found to be $\chi = \frac{1}{\epsilon_0} \frac{dP}{dE} \Big|_{E=0} = \frac{1}{a + 3bP^2} \Big|_{E=0} = \frac{1}{\zeta|a|}$ according to Eqs. (2) and (3), where $\zeta = 1$ in the paraelectric state ($P = 0$) and $\zeta = 2$ in the ferroelectric one ($P \neq 0$). Consequently, the Curie-Weiss behavior $\chi \propto |T - T_c|^{-1}$ illustrated in Fig. 5(b) is naturally reproduced within the LGD theory. Similarly, the pyroelectric coefficient becomes $\gamma = \frac{dP}{dT} \Big|_{E=0} \propto |T - T_c|^{-1/2}$, which also diverges and tends to infinity near the transition point but with different scaling. Divergences of this type, however, end up into discontinuities if the spontaneous polarization changes abruptly from zero in the paraelectric phase to a finite value in the ferroelectric one.

The simplest way to reproduce a discontinuous (or first order) transition is to assume that $b < 0$ in Eq. (1) and to introduce the next higher-order term $\mathcal{O}(P^6)$ to bound the energy from below. This is in fact the case of most ferroelectrics, and in particular in the ferroelectric perovskites like BaTiO₃ (see Fig. 6), which is still compatible with the LGD approach if the discontinuity is relatively small. Such a discontinuity can be due to a number of different factors, but sometimes can be interpreted as due to the coupling between the electric polarization and other degrees of freedom that tacitly assumed to minimize the potential energy for a given P and therefore do not appear explicitly in Eq. (1). In those cases, a generalized LGD energy expanded not only in terms of P but also in terms of secondary variables such as strain may be invoked. The symmetry properties of these variables then determine the possible coupling terms (but obviously not their strength).

To illustrate this, let us consider the relative variation of the volume (i.e., the dilatation) u as such a secondary variable and supplement Eq. (1) with the terms $gP^2u + \frac{K}{2}u^2$. Here the first one represents the coupling term and K is the bulk modulus. The minimization of the overall potential energy with respect to the new variable implies $u = -\frac{g}{2K}P^2$. Thus, the added terms become $-\frac{g^2}{2K}P^4$ so that the actual coefficient of the eventual $\mathcal{O}(P^4)$ term reads $b - \frac{2g^2}{K}$. Consequently, if $b > 0$ but $b < \frac{2g^2}{K}$ then the transition can be interpreted as discontinuous due to the dilatation u since it would be otherwise continuous in a clamped ($u = 0$) system.

This treatment can also be generalized by considering the electric polarization as a field $P(\mathbf{r})$ rather than just a constant variable. Thus, it is possible describe states that are spatially inhomogeneous. The LGD energy then becomes a functional where the extra energy associated to a non-uniform P implies both local gradient terms and non-local interactions mediated by electric field that appears due to such a non-uniform P according to Gauss's law. By including the extra variables that describe inhomogeneous elastic strains then the non-local character of the solid-state elasticity can also be incorporated as well.

In fact, there are a number of inhomogeneous states that are relevant in relation to ferroelectricity. For example, in the aforementioned example, in which the coefficient of the $\mathcal{O}(P^4)$ term becomes negative due to the dilatation, an equilibrium two-phase state can be formed where a part of the system remains in the non-polar state while another part undergoes the polar distortion. A more important example is phase transition in a slab without electrodes with the polar axis perpendicular to the slab plane. It proves that the loss of stability of the non-polar phase occurs here not with respect to homogeneous polarization but with respect to inhomogeneous (sinusoidal) distribution of the polarization along the slab. In experiment this distribution can be observed only in special conditions (very thin slabs) because it converts into usual domain structure (see below) already in a near vicinity of the transition.

In the spirit of the Landau theory, energy expansions like Eq. (1) represent an expansion about the point at which the initial (paraelectric) state becomes unstable with respect to the corresponding order parameter (P), so that this order parameter appears "spontaneously" to minimize the energy thereby breaking the symmetry of the system (from a non-polar to a polar structure in the simplest ferroelectric case). Note that $P \propto E^{1/3}$ at $a = 0$ according to Eq. (2), so that $P/E \rightarrow \infty$ in the limit $E \rightarrow 0$ at that point. Thus, it is not surprising that in ferroelectrics $P \gg \epsilon_0 E$, i.e., $P \approx D$.

Applicability of the LGD theory

Formally, the LGD theory can be related to a partition function in which all the internal degrees of freedom but P are integrated out, i.e., $Z(P; E) = \text{tr}'(e^{-\hat{H}/k_B T})$ where tr' denotes such a partial integration. The LGD free energy then can be regarded as the power series expansion of $F_{\text{LGD}}(P; E) = -k_B T \ln Z(P; E)$. The temperature dependence of the LGD free-energy coefficients is a natural consequence of this formal derivation. In practice, however, such a calculation is out of reach unless some approximations are

Fig. 6 Spontaneous polarization (a) and dielectric constant (b) measured as a function of temperature in BaTiO₃. The initial ferroelectric transition at $\sim 120^\circ\text{C}$ is discontinuous. This transition is followed by structural transitions in which the direction of the polarization changes as indicated at the top of (a). From Strukov BA, and Levanyuk AP (1998) *Ferroelectric Phenomena in Crystals*. Berlin: Springer. p. 21.

made. These approximations justify the simple LGD power-series expansion relatively close to the transition point. However, they become invalid right at the (second-order) transition point due to the extreme specificity of this point. This is exemplified by Onsager's exact solution of the two-dimensional Ising model, which demonstrated that the behavior of this model at the transition point is fundamentally different compared to that obtained according to the Landau theory. It took several decades until this contradiction was resolved, which is considered as one of the main achievements of theoretical physics of the 20th century. Accordingly, the asymptotic behavior of various physical quantities is described in terms of "critical exponents" and there appears the notion of universality class (i.e., a group different models displaying the same critical exponents, which is eventually determined by their symmetry properties alone). Using renormalization group techniques, it was shown that the numerical value of these exponents can be calculated with reasonable accuracy.

At the same time, it was also understood that, apart from the immediate vicinity of a second-order transition, the Landau theory remains applicable in a number of realistic models. Thus, it can successfully describe many physical situations of interest. This is precisely the case of most of the conventional ferroelectrics due to some distinct features of these systems (characteristic energy scales and long-range interactions, together with the fact that in many cases the transition is discontinuous). Also, the critical behavior is extremely sensitive to disorder and defects so that the theoretical behavior expected in the ideal case is practically never observed for real ferroelectric materials. So, in practice, the LGD level of description is generally justified as a reasonable approximation.

Of more practical importance than inapplicability of the Landau theory in immediate vicinity of the instability point are inherent limitations of this theory which may hamper its consistent applications beyond this vicinity. Landau made use of a simple idea that the loss of stability is practically always with respect to a single ("critical") degree of freedom. This means that close to the instability (which coincides with the transition point for the second order transitions which this theory is about) the structural changes resulting from the stability loss can be characterized by a single variable to a good approximation (the closer the instability point the better this characterization is). In the case of proper ferroelectrics, this degree of freedom is polar by symmetry and very "soft" close to the instability point by definition. Its response to an electric field is then huge and, accordingly, dominates the total electric polarization over the contribution of the rest of polar degrees of freedom. This circumstance justifies the use of the polarization as the order parameter in the LGD theory and is the reason of its so attractive simplicity. However, it is also a reason for its limitation.

The identification of the total electric polarization with a single critical degree of freedom may become insufficient for the quantitative description of the actual structures and their properties at some distance of the instability. This has led to "extensions" of the LGD theory in which "non-critical" polar degrees of freedom, characterized via an empirical "base dielectric constant," are taken into account. This enables the qualitative explanation of experimental data in some cases. This type of extensions, however, spoils the universality of the LGD theory to become a case-by-case model (Levanyuk et al., 2016).

The shortcoming of identifying the electric polarization with the critical degree of freedom becomes most evident when the polar structure emerges in a metal such as LiOsO_3 . In this case the polarization is screened by the free electrons, yet the polarity of the structure can still be reversed if this screening is somehow weakened as in ultrathin films. These special ferroelectrics are called ferroelectric metals (Zhou and Ariando, 2020).

The LGD approach, however, has no predictive power when it comes to material-specific quantitative questions such as the actual value of the spontaneous polarization and response functions such as the dielectric constant or, more generally, the precise chemical compositions that can host ferroelectricity. This motivates the development of complementary theoretical tools based on first principles, which have been demonstrated particularly successful in the context of ferroelectric materials (see e.g., Rabe et al., 2007). In particular, the electronic contribution to the variations of the polarization has been reformulated as a geometric quantum (Berry) phase, which is exploited in density-functional-theory calculations to compute not only the macroscopic polarization but also dielectric and piezoelectric tensors. However, the presence of defects and electrochemical effects still represents a challenge for the theoretical description of ferroelectricity in real systems.

Displacive vs order-disorder limits

More microscopically, the emergence of ferroelectricity is often regarded as either the displacive or the order-disorder limit of a structural phase transition.⁷ To illustrate these two limits, let us consider a simple model of a one-dimensional crystal with two atoms per unit cell interacting via short-range potentials. Specifically, we consider intracell and intercell interactions between nearest cells only. Also, we assume that the atoms can be considered as classical particles (i.e., their masses are such that quantum effects can be neglected). This simple model is sketched in Fig. 7 (see also Strukov and Levanyuk, 1998).

⁷This can be additionally motivated by the characteristic energy scales that can be associated with ferroelectricity. In addition to the corresponding transition temperature T_c , some materials display another energy scale that matches the so-called atomic temperature $T_{at} \sim 10^4 - 10^5 \text{ K}$ as deduced, for example, from the Curie-Weiss behavior of the electric susceptibility $\chi \sim C / |T - T_c|$ according to the Curie-Weiss constant C . The displacive limit corresponds to a situation dominated by interatomic interactions, which then provide T_{at} as a relevant energy scale. The instability behind the phase transition, and hence the corresponding value of T_c , results from the accidental cancelation of different energy contributions in this case. The order-disorder limit, in contrast, corresponds to a situation in which thermal effects play the key role with T_c as the only energy scale.

Fig. 7 (a) Sketch of a one-dimensional crystal with two atoms per unit cell undergoing a structural transition from a non-polar to a polar structure. (b) and (c) Effective model of the crystal. The balls indicate the relative displacement of the atoms in (a) while the curves represent the effective potential due to the intracell interactions and the springs model the (repulsive) intercell interactions.

In the displacive limit, the essential ingredient that produces the phase transition is the change of the intracell potential from Fig. 7(b and c). Accordingly, the particles undergo a relative displacement such that they shift from their initial centered positions either leftwards or rightwards, thereby breaking the symmetry of the crystal. The collective character of this phenomenon is enforced by the intercell interactions modeled by the springs, since they result in an energy penalty whenever the particles displace differently at different positions in the crystal.

In the order-disorder limit, in contrast, the intercell potential is always like in Fig. 7(c) and the key ingredient is the temperature.⁸ At zero temperature all particles will be ordered, either leftwards or rightwards, as before. At finite temperature, however, the particles have a non-zero kinetic energy and their positions fluctuate. These fluctuations will destroy the low-temperature order toward more complex, globally disordered configurations in which the average displacement will be zero if the temperature is high enough. Effectively, this can be expected to occur when the thermal energy per particle ($k_B T$) becomes comparable with the change in potential energy obtained when one particle is at the “wrong” minimum of the intracell potential (i.e., comparable with intercell interactions modeled by the springs).

Note, however, that these two limits correspond to rather idealized situations. Thus, it is not surprising that real ferroelectrics may display features related to both these limits. Even for the above simple model, a mixed displacive and order-disorder behavior is to be expected if the springs are not totally rigid and/or the potential minima are not extremely narrow. In fact, at finite temperature, the order in a nominally displacive system can be expected to disappear before reaching the point at which the intracell potentials change from double- to single-well potentials due to thermal fluctuations. That is, a nominally displacive transition can be expected to become, in effect, an order-disorder one close enough the corresponding transition temperature. Similarly, at zero temperature, quantum zero-point fluctuations and/or tunneling may restore the symmetry of the system even if the intracell potentials remain double-well potentials.

Dynamics

The electric polarization in conventional ferroelectrics is directly related to collective changes in the atomic positions. In the aforementioned displacive limit, its equation of motion in the classical limit at zero temperature can be written as

$$m \frac{d^2 P}{dt^2} + aP + bP^3 = E(t). \quad (4)$$

This is essentially the equation of motion of a nonlinear (anharmonic) oscillator driven by the external field. The first (inertial) term is associated with the kinetic energy of the collective motion. In the paraelectric phase, the nonlinear term can be neglected if the amplitude of the oscillations is small enough.⁹ Then, the natural frequency of the oscillator is $\omega_0 = \sqrt{a/m}$ and therefore tends to zero as $a \rightarrow 0$ near the transition point. In this sense, the electric polarization is associated to a soft mode of the system.

The realistic generalization of Eq. (1) to finite temperatures, however, remains a challenge. In particular, it is necessary to describe the energy dissipation from the polarization mode to the rest of degrees of freedom of the system, which ideally represent an energy reservoir. The simplest attempt consists of introducing a dissipation term the form $\gamma \frac{dP}{dt}$.

In the order-disorder limit, in contrast, the motion is dominated by thermal activation as explained above. This situation formally matches the extreme overdamped regime ($m = 0$). The temporal processes are characterized by the relaxation time $\tau = \gamma/a$ which tends to infinity as $a \rightarrow 0$.

⁸Note that the model reduces to the Ising model when the potential wells are extremely narrow. In this case, the atoms can take only two positions so that their relative displacement becomes a discrete Ising variable $\pm u_0$ (rather than a continuous one).

⁹In the ferroelectric phase ($a < 0$), the non-linear term becomes essential even for small oscillations since Eq. (4) needs to be expanded about the equilibrium polarization.

In reality, this description oversimplifies the actual dynamics of P . As indicated in the previous section, the behavior of a real ferroelectric can evolve from the displacive limit to the order-disorder one as the transition temperature is approached. According to the above simplified dynamics, a soft mode should simply become overdamped sufficiently close to the transition if this is continuous. Before this happens, however, the displacive to order-disorder crossover often takes place and complicates the situation. Thus, the dynamics may remain essentially vibrational at high frequencies, but it can be expected to become relaxational at low frequencies. Experimentally, in fact, the frequency of the soft mode ceases to decrease when the transition is approached while its spectral weight, as measured in Raman experiments for example, is transferred to a low-frequency feature (i.e., the so-called central peak, see e.g., Ginzburg et al., 1980) whose integrated intensity diverges despite its width tends to zero.

Domains, domain walls and ferroelectric textures

According to Eqs. (1) and (2), there is an energy barrier for the polarization reversal from metastable to equilibrium states (see Fig. 4). This barrier formally disappears beyond a certain field $E_c^{(0)}$ that would determine the so-called thermodynamic coercive field.¹⁰ In practice, however, the reversal is already possible at much lower fields (typically one or two orders of magnitude lower than $E_c^{(0)}$). The actual switching involves a number of processes some of which are still not well understood (Tagantsev et al., 2010). First, a nominally homogeneous polar sample can in fact contain “frozen-in” regions of opposite polarization that expand when the external field is applied. Second, the polarization can be initially reversed locally only in some regions and then these regions can grow and spread out to the entire sample (see Fig. 8). The nucleation of these regions is believed to occur at the boundaries of the sample or at volume defects, and their form is such that the corresponding depolarizing field is minimized since this field strongly contributes to the overall energy. The precise details of this “nucleation and growth” process, however, remain unclear. In particular, the estimates of both the critical dimensions and critical energy of the nucleation centers yield values that are hardly achievable by means of thermal fluctuations without the assistance of some defects or imperfections.

In any case, states with nonuniform polarization can be obtained not only during the polarization reversal but also when the system driven to the ferroelectric phase from the non-polar (paraelectric) one. The regions in which the polarization is in a uniform direction are called domains and the boundaries between these regions are dubbed domain walls. The formation of domains at phase transitions is inherent to the process of spontaneous symmetry breaking. In fact, different domains represent different possible variants of such a symmetry breaking that are energetically equivalent and they can be obtained one from another by the symmetry transformation that disappears due to the breaking.

The macroscopic structure of the domains and more microscopic details such as the structure of the domain walls—typically of a few unit cells—can be studied by means of different techniques spanning from etching and optical methods to atomic force and electron microscopy (Tagantsev et al., 2010). In general, there is an energy penalty associated with the presence of domain walls so that the formation of domains implies either a metastable state or an energy gain somewhere else compensating such a penalty. For example, if the spontaneous polarization is perpendicular to the boundary of the sample, then there will be an electric field created by the corresponding bound charges at the surface Σ since $\nabla \cdot \mathbf{P}|_{\Sigma} \neq 0$ —i.e., the so-called depolarizing field. In that case, the energy of such a field can be reduced by the formation of domains despite the energy associated to the corresponding domain walls. However, if the surface bound charges are screened via the free carriers of metallic electrodes for example, then the domain-wall penalty will tend to favor the single-domain configuration. In fact, in many ferroelectrics, the application of even moderate electric field makes the crystal single domain.

The ferroelectric domain patterns can be quite diverse, especially in a multiaxial ferroelectric and even for the same crystal. However, there are some regularities, especially when it comes to the orientations of the domain walls. In conventional ferroelectrics, the domain walls tend to be such that the component of the polarization perpendicular to wall is continuous. In this way, no bound charge is generated and the domain wall remains neutral, thereby avoiding an extra electrostatic-energy penalty. Likewise, the domain walls tend to orient in such a way that the elastic energy is also minimized (which yields the so-called mechanical compatibility conditions for the polarization-induced strains). The charge-neutrality condition can be violated by creating free carriers to screen the bound charges. This leads to enhanced conductivity at the domain walls, with values that can approach metallic regimes in some cases. The domain walls then become reconfigurable two-dimensional conducting channels in otherwise insulating media, with additional properties analogous to some electronic devices (e.g., electronic switches).

Fig. 8 Schematic representation of the polarization reversal via nucleation and growth process. The white/grey areas represent regions with opposite polarization.

¹⁰Note that thermodynamic coercive field would be associated with a process in which the polarization reversal occurs homogeneously and simultaneously across the whole ferroelectric.

In nano systems and in particular in multilayers, the interplay between depolarizing field, elastic, and gradient energy contributions can lead to complex ferroelectric textures with the electric polarization pointing in different directions. These range from the so-called flux-closure configurations to ferroelectric vortices and skyrmions, whose names announce topological properties (Das et al., 2020). Beyond that, the electric polarization in some special ferroelectrics can emerge as a by-product of another symmetry breaking and not as a primary order parameter by itself (see section “Improper ferroelectricity”). Then, if the primary order parameter displays some sort of texturing, this can be transposed to the electric polarization. The emergence of charged domain walls can be enforced in this way.

Ferroelectricity in liquid crystals and incommensurate ferroelectrics

In some liquid crystals, the so-called chiral smectics, there exists spontaneous polarization that changes its direction (“winds”) if one translates along a special direction of these systems. The winding is periodic with a macroscopic pitch: 5–10 μm . The polarization can be made homogeneous by applying a relatively small electric field (Strukov and Levanyuk, 1998).

Another type of spatially inhomogeneous polarization, with changing magnitude rather than direction, is observed in some ordinary (solid) crystals. In this case, the period of the inhomogeneity just one or two orders of magnitude larger than the interatomic distance. It changes with temperature independently of the period of structural features that do not contribute to the polarization (“basic lattice”). The crystal has two independent (“incommensurate”) periodicities. At some temperature, the polarization becomes homogeneous (within macroscopic domains), that is, there is a phase transition between the incommensurate and the ordinary (“commensurate”) ferroelectric phase. This phase transition belongs to a special class of transitions (“lock-in transition”), which take place not only in ferroelectric but in many other systems, for example, in systems with charge density waves. In ferroelectrics, this transition is usually accompanied by a strong increase of the dielectric constant (Strukov and Levanyuk, 1998).

Improper ferroelectricity

In some materials, ferroelectricity appears not as a result of the instability with respect to P itself but as a non-linear effect arising in relation to symmetry breakings other than the non-polar to polar one (e.g., translational symmetry breaking as in all such cases reported so far, see Strukov and Levanyuk, 1998). These systems are called improper ferroelectrics and the notion of primary (Q) vs secondary (P) order parameters beyond the LGD paradigm becomes particularly helpful to describe their basic properties.

By definition, the primary order parameter Q of improper ferroelectrics has to be a multi-component quantity since the spontaneous polarization P cannot be simply proportional to it (otherwise Q and P would be equivalent from the symmetry point of view). In the simplest case, the primary order parameter is a two-component quantity $Q = (Q_1, Q_2) = Q(\cos \Phi, \sin \Phi)$ and the electric polarization is $P \propto Q^n \cos(n\Phi)$ (or $\cos \leftrightarrow \sin$). Here, n is an integer that depends on the specific system under consideration ($n = 2$ in gadolinium molybdate and $n = 3$ in the hexagonal manganites for example). Such a P - Q relationship is determined by symmetry. Within the Landau theory, it can also be derived from a generalized energy expansion in terms of both Q and P under the same conditions of applicability than for standard ferroelectrics (that is, for continuous or weakly discontinuous transitions whenever critical fluctuations can be neglected). Thus, it can be understood that, while the corresponding constitutive $P(E)$ equation can lead to similar hysteresis loops as in the standard proper case, the dielectric susceptibility displays a discontinuity rather than a Curie-Weiss-like divergence.

Further, the actual domains of improper ferroelectrics are fundamentally determined by the primary order parameter and not by the spontaneous polarization alone. Likewise, the domain walls and the topological defects that can emerge in these systems are more complex objects with additional features compared to standard ferroelectrics. This facilitates the emergence of some special domain patterns with charged domain walls as illustrated in Fig. 9.

To further elaborate on this point, let us consider the particular case of the hexagonal manganites. In this case, the variable Φ appears in the Landau energy expansion via the term $gQ^6 \cos(6\Phi)$ after minimization over P . Neglecting higher order terms, then the extrema of the free energy imply either $\Phi_k = k\pi/3$ or $\Phi_k = (2k + 1)\pi/6$ with $k = 0, 1, \dots, 5$. Which type of solution corresponds to the minima—i.e., equilibrium states—depends on the sign of the coefficient g (which in its turn depends on the coupling to P).¹¹ These two sets of solutions define 6 polar states and 6 non-polar states. The 6 polar states, in their turn, correspond to 3 + 3 domains with opposite polarity. Then, unlike in proper ferroelectrics, there are now structural changes that leave the electric polarization unchanged (e.g., a translation by the unit cell of the non-polar structure, which is no more a symmetry operation of the polar phase). Consequently, there can be domain walls between different domains whose electric polarization, however, is same. Besides, the domain structure in these systems may display “topological defects” whose nature is qualitatively different compared to those that appear in proper ferroelectrics. The defects shown in Fig. 9, in particular, corresponds to 6 structural domains that meet at a singular line.

¹¹The general phase diagram, however, can include not only the transition between the $Q = 0$ phase and one type of $Q \neq 0$ solution, but also the additional transition between different $Q \neq 0$ phases (i.e., the two phases determined by the two sets of Φ_k 's).

Fig. 9 Characteristic domain patterns observed in hexagonal magnanites (the arrows indicate the direction of the electric polarization). Left. Domain pattern with singular points from which there emerge six domains. The arbitrary inclination of the corresponding domain walls leads to bound charges and hence charged domain walls. Right. Conductive atomic force microscopy (c-AFM) image showing the different conductivity at the ferroelectric domain walls compared to the domains, which is linked to their charge. From Meier D, et al. (2012) Anisotropic conductance at improper ferroelectric domain walls. *Nature materials* 11(4): 284–288.

Multiferroics

The functional properties of ferroelectrics can be augmented by magnetic order like in the so-called type-I multiferroics (e.g., BiFeO_3 or the hexagonal manganites). In these systems ferroelectricity remains a purely structural phenomenon that emerges independently of the magnetism. However, ferroelectricity (either proper or improper) can also result from magnetic order itself and therefore be driven by spins. The systems materializing this latter possibility are called type-II multiferroics (Fiebig et al., 2016; Spaldin and Ramesh, 2019; Cano et al., 2021). The spontaneous electric polarization of type-II multiferroics is due to magneto-structural couplings. Consequently, its magnitude as well as the strength of the accompanying magnetoelectric effects depend on whether these couplings are due to relativistic effects or not. In general, the couplings trace back to either symmetric exchange interactions (e.g., Heisenberg exchange), antisymmetric exchange (Dzyaloshinskii-Moriya interaction), or both (see e.g., Bousquet and Cano, 2016). Non-centrosymmetric magnetic orders compatible with a spin-driven spontaneous polarization include the collinear *E*-type antiferromagnetic order displayed by the orthorhombic HoMnO_3 and the non-collinear cycloidal order observed in TbMnO_3 . In addition, spin textures such as Néel domain walls in ferromagnets also break inversion symmetry and can locally induce an electric polarization.

Ferroelectricity beyond the Landau paradigm

As we have mentioned above, ferroelectrics are essentially pyroelectrics whose spontaneous electric polarization can be reversed due to some sort of softness of the system. We find it prudent and even compulsory to leave such a “softness” without strict definition. The reason is that, even if it can be described—case-by-case—in already known materials, it is hard to catalog and even harder to anticipate all its possible realizations.

In fact, for a century after the discovery of the first ferroelectric it was enough to associate this “softness” to the structural vicinity to another non-polar—and hence more symmetric—phase of reference. This vicinity is further the key for the success of the Landau theory-based description and classification of ferroelectrics. The reason is that it enables a description in terms of a single variable (i.e., the order parameter) with respect to which the reference (non-polar symmetric) phase loses its stability. This loss of stability is inherent in the phenomenon of the spontaneous symmetry breaking when the change of the symmetry can be achieved by any, even infinitely small, changes of atomic positions if the directions of these changes are properly defined.

More recently, however, it has been realized that this is not the only way to perceive reversible polar structures (Wu and Li, 2021). Rather than due to the vicinity to a loss of stability and the smallness of the corresponding structural changes, the softness can be effective simply due to the relative weakness of the atomic bonds themselves as in the so-called van der Waals materials. These materials can easily realize different stacking variants, either stable or metastable, some of which can be polar (see Fig. 10). Then, the polarization can be reversed by transforming one stacking into another. This generally requires a finite-distance shift in one or several directions, which however can be obtained by applying an electric field. This phenomenon was called “sliding ferroelectricity.”

The classification of ferroelectrics used so far in this chapter is essentially based on the notion of order parameter and symmetry aspects as defined within the Landau theory. However, when trying to include sliding ferroelectricity within such a classification, we realize that no consistent description can be made in the spirit of the Landau theory (in particular, no order parameter can be identified). This forces us to introduce a new category and call this type of ferroelectricity non-Landau ferroelectricity.

To explain the situation, let us compare the energy profiles of the Landau and non-Landau ferroelectrics illustrated in Fig. 10. At first glance, the two profiles look the same. However, there is a very important fundamental difference between them: while the

Fig. 10 Top panels: Illustration of different stackings associated to non-polar and polar structures than can be realized in non-Landau ferroelectrics like hexagonal boron nitride. The polarization in these systems can be reversed by in-plane interlayer sliding (so that the stacking changes from BA to AB or vice versa). Bottom panels: Energy landscape of Landau vs non-Landau ferroelectrics. While the former can be tuned by means of the control parameter, the latter is fixed and determined by the bondings. Adapted from Tsymlal EY (2021) Two-dimensional ferroelectricity by design. *Science* 372(6549): 1389–1390.

energy barrier and the distance between the two minima can be varied by means of the corresponding control parameter in the Landau case, they are fixed and essentially determined by the bondings in the non-Landau ferroelectric. Specifically, the point at which the barrier disappears and the distance is zero can be reached by varying the control parameter in the Landau case. This point is precisely the point at which the non-polar phase loses its stability. As emphasized above, the very existence of this point and its vicinity turns out to be fundamental for the success of the Landau-theory reasonings. The situation, however, is fundamentally different in the non-Landau case since the appearance of ferroelectricity cannot be traced back to any loss of stability. Consequently, there is no evident control parameter by means of which the energy barrier and/or the distance between the energy minima can be tuned to disappear. In this sense, the shape of the energy landscape is fixed in the non-Landau case. Of course, a theory as simple and effective as the Landau theory is highly desirable to describe these systems. At present, however, this is theory does not exist and it looks like a rather challenging problem.

Conclusion

Ferroelectricity in traditional ferroelectric materials is now a rather well understood phenomenon that can be characteristically denoted as emergent. In that case, the Landau theory of phase transitions provides a convenient starting point that can be further combined with microscopic models and *ab initio* descriptions to describe the distinct properties of ferroelectric systems. These properties promote a number of functionalities that can be supplemented with magnetic order in multiferroics and even metallicity. These multi-faceted functionalities span different length scales, from macroscopic behavior to the atomic scale, and can be engineered via the control of ferroelectric domains and domain walls as well as via the growth of heterostructures. This enables an increasing number of ferroelectricity-based applications, especially in electronics among other fields. Further, a new class of ferroelectric materials beyond the Landau paradigm has appeared recently. Ferroelectricity in these new systems does not have an immediate emergent character and thus calls for a new theoretical framework.

Abstract

A brief discussion on the theoretical aspects of electron states in planar quantum dots is presented in this chapter. Some common models of electron confinement, such as rectangular and parabolic confining potentials are analyzed in detail. The deviations from the isotropy and parabolicity of the confinement are also considered in the light of the application of some well-known models such as the Woods-Saxon potential in planar quantum dot systems. Further, appearance of Fock-Darwin states in a quantum dot with parabolic confinement in a uniform magnetic field is discussed. A special attention is devoted to the electron-electron Coulomb interaction in planar quantum dots. Finally, the appearance of magic numbers and the Maksym-Chakraborty effect for Fock-Darwin states connected with the interplay of parabolic confinement and the inter-particle interactions is discussed.

Key points

- Quantum dots are fascinating objects which can have technological applications in many different fields.
- Planar quantum dots are nanosized semiconductor islands where electrons behave like 2D quasi-particles.
- Planar quantum dots are ideal systems for observation of Fock-Darwin spectrum and Landau levels.
- In quantum dots with parabolic confining potential far infrared spectrum is not affected by electron-electron interaction.
- In planar quantum dots with many electrons the ground state in a magnetic field occurs only at certain magic values of angular momentum.

Introduction

It is well known that the decrease of the geometric sizes of a specimen to the values of the order of the de Broglie wavelength of quasi-particles gives rise to the quantization of their motion in the specimen (Fröhlich, 1937) and, therefore to discrete energy levels. Quasi-particles in semiconductors have relatively large de Broglie wavelength, in particular, because of relatively small effective masses. With recent advances in crystal growth and processing techniques, it is possible to confine electrons and holes in extremely thin semiconductors with nanometer dimensions. Band gaps of semiconductors can be tuned by varying specimen sizes and when the size of the specimen decreases to the order of the electron de Broglie wavelength, the structures obtain new electronic and optical properties due to the size quantization (Guozhong, 2004). This procedure can be developed by further reducing the dimensionality of the specimen from a two-dimensional quantum well (QW) to a one-dimensional quantum well wire (QWR) and eventually to a zero-dimensional quantum dot (QD) (Davies, 1998; Harrison and Valavanis, 2016). In this context, the dimensionality refers to the number of degrees of freedom in the electron motion. The continuing reduction of dimensional features in electronic and optoelectronic devices coupled with revolutionary advances in semiconductor growth and processing technologies have opened many avenues for increasing the performance levels and functionalities of electronic and optoelectronic devices. Moreover, the advanced nanotechnologies lead to further revolutionary breakthroughs such as those exemplified by quantum dot semiconductor lasers, double barrier quantum dot diodes operating in the terahertz frequency range, single electron transistors, quantum dot solar cells and displays, etc. (Xi and King, 2012).

In this chapter the theoretical approaches of the so called planar (two-dimensional) semiconductor QDs will be described. In general, a semiconductor system can be considered as strictly two-dimensional only if the lowest two-dimensional subband is

occupied. This is the same as the condition that the Fermi energy lies far below the second subband, or stated differently, as the condition that the thickness of the planar QD is much less than the average separation of the electrons. Similar conditions also hold for one-dimensional systems. In case of QDs the system can be considered as two dimensional if the energy separation of two neighboring discrete levels related to growth direction is much larger compared with energy separation for in-plane directions. Low-dimensional electron systems are, therefore, low dimensional only in the dynamical sense.

In section “Confinement models and the energy spectra” of this article the different models of confining potential for isotropic and anisotropic planar QDs will be described. In section “Quantum dot in a magnetic field: Landau levels vs the Fock-Darwin states” the effect of external magnetic field on energy spectra of planar QDs will be considered. Finally in section “Electron-electron interactions in QDs” the effect of electron-electron interactions will be discussed.

Confinement models and the energy spectra

Quantum dots, also popularly known as “artificial atoms” (Alivisatos, 1996; Bimberg et al., 1998; Chakraborty, 1999), in which the confining potential replaces the potential of the nucleus, are fascinating objects which can have and already have technological applications in many different fields such as memory chips, quantum computations and cryptography, room temperature quantum dot lasers (Steiner, 2004), quantum dot solar cells (Sogabe et al., 2016), bioimaging applications (Bera et al., 2010), etc. The semiconductor quantum dots are mostly semiconductor heterostructures in which a small island of narrower band-gap semiconductor (dot material) is inserted inside the matrix of wider band-gap semiconductor (barrier material). These types of quantum dots are mostly created using self-assembly growing technology (Henini, 2008).

The self-assembled quantum dots mostly have cylindrical symmetry and the size of the dot in growth direction (z -direction) is much smaller compared with planar sizes of the dot: $L_z \ll R$ or for a specimen with longitudinal sizes L_x and L_y , $L_z \ll L_x, L_y$. Due to the strong size quantization effect in the z -direction the energy difference between the first two lowest energy levels $\Delta E_{\perp}$ in that direction will be proportional to $\hbar^2/mL_z^2$, where m is the effective mass of the quasi-particle in the dot material. On the other hand the energy difference between neighboring states for the lateral direction $\Delta E_{\parallel} \sim \hbar^2/mR^2$, where R is the lateral radius of the dot. Since $L_z \ll R$, one can assume that $\Delta E_{\parallel}$ is much smaller than $\Delta E_{\perp}$, and all electrons in the QD will occupy only the ground state related to the z -direction. Therefore, one can assume with high accuracy that the particle motion in the z -direction is frozen and the system can be considered as 2D or planar.

Within the frame of the effective mass approximation the single-electron Schrödinger equation in a planar quantum dot has the form:

$$\left[-\frac{\hbar^2}{2m}\Delta + V_{\text{conf}}(x,y) \right] \psi(x,y) = E\psi(x,y), \quad (1)$$

where Δ is the 2D Laplace operator and $V_{\text{conf}}(x,y)$ is the confining potential of the dot. Thus one of the first steps of theoretical modeling of planar QDs is the construction of a confining potential of the dot. Here we will consider several models for the confinement.

Square well model

One of the most simple and widely used models for a confining potential of planar QDs is the square well model:

$$V_{\text{conf}}(x, y) = \begin{cases} 0, & \sqrt{x^2 + y^2} \leq R, \\ V_0, & \sqrt{x^2 + y^2} > R. \end{cases} \quad (2)$$

This model describes a disk-shaped planar QD obtained using abrupt semiconductor heterojunctions. In Eq. (2) V_0 is the height of the potential barrier, which can be determined from the band gap difference ΔE_g between two semiconductors making the QD: $V_0 = Q_e \Delta E_g$, where Q_e is the conduction band discontinuity fraction. For example, in GaAs/Ga_{0.7}Al_{0.3}As heterostructure $\Delta E_g = 374.1$ meV, $Q_e = 0.6$ and $V_0 = 225$ meV (Adachi, 2004; Vurgaftman et al., 2001).

For a circular QD the Schrödinger equation (1) will be easier to solve in polar coordinate systems:

$$\left[-\frac{\hbar^2}{2m} \left(\frac{\partial^2}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial}{\partial \rho} + \frac{1}{\rho^2} \frac{\partial^2}{\partial \varphi^2} \right) + V_{\text{conf}}(\rho) \right] \psi(\rho, \varphi) = E\psi(\rho, \varphi), \quad (3)$$

where $V_{\text{conf}}(\rho) = 0$ if $\rho \leq R$ and $V_{\text{conf}}(\rho) = V_0$ otherwise. We can search the solution of Eq. (3) in the form

$$\psi(\rho, \varphi) = \frac{C}{\sqrt{2\pi}} \exp(i l \varphi) f(\rho), \quad (4)$$

where C is the normalization constant, the angular quantum number l due to the periodicity condition $\psi(\rho, \varphi + 2\pi) = \psi(\rho, \varphi)$ takes the values $l = 0, \pm 1, \pm 2, \dots$ and $f(\rho)$ is the radial wave function. By substituting Eq. (4) into Eq. (3) one can obtain an equation for the radial wave function $f(\rho)$:

$$\left[-\frac{\hbar^2}{2m} \left(\frac{d^2}{d\rho^2} + \frac{1}{\rho} \frac{d}{d\rho} - \frac{l^2}{\rho^2} \right) + V_{\text{conf}}(\rho) \right] f(\rho) = E f(\rho). \quad (5)$$

It is easy to show that the solution of Eq. (5), satisfying to conditions of continuity and finiteness of the wave function, can be expressed by the Bessel function $J_l(x)$ and the Macdonald function $K_l(x)$ (Abramowitz and Stegun, 1970):

$$f(\rho) = \begin{cases} J_l(\alpha\rho), & \rho \leq R, \\ \frac{J_l(\alpha R)}{K_l(\beta R)} K_l(\beta\rho), & \rho > R, \end{cases} \quad (6)$$

where $\alpha = \sqrt{2mE/\hbar^2}$ and $\beta = \sqrt{2m(V_0 - E)/\hbar^2}$. Since here we are interested only with bound states in the QD, we will assume that $E < V_0$.

The energy eigenvalues of the QD can be obtained using the continuity condition of the first derivative of the radial wave function $f(\rho)$ at point $\rho = R$:

$$\left. \frac{dJ_l(\alpha\rho)}{d\rho} \right|_{\rho=R} = \frac{J_l(\alpha R)}{K_l(\beta R)} \left. \frac{dK_l(\beta\rho)}{d\rho} \right|_{\rho=R}. \quad (7)$$

By solving Eq. (7) numerically for given values of R , V_0 and l one can obtain the energy levels of the QD in the range $0 \leq E \leq V_0$. For the given value of angular quantum number l the energy eigenvalues of the QD can be numbered from the lowest to the highest using the analog of the radial quantum number $n = 1, 2, 3, \dots$. Therefore each quantum state in a QD can be described using two quantum numbers n, l , i.e., $|n, l\rangle$ and the corresponding energy will be E_{nl} . It should be also noted that each state of the QD is degenerate by the sign of l and also doubly degenerate due to the spin of the electron.

In Fig. 1 the dependence of the first few energy levels of a QD with square well potential on the radius of the QD are presented for various values of the angular quantum number l . Calculations are performed for the GaAs/Ga_{0.7}Al_{0.3}As QD with parameters $m = 0.067m_0$ (m_0 is the free-electron mass) and $V_0 = 225$ meV. For all values of the QD radius the ground state energy is E_{10} . With the increase of R the ground state energy decreases and tends to 0 (the bottom of the conduction band for the dot material). In the classical limit ($R \rightarrow \infty$) the distances between the neighboring energy levels tend to 0 and the continuous spectra will be obtained. For another limiting case $V_0 \rightarrow \infty$ from the boundary condition at point $\rho = R$ we get $J_l(\alpha R) = 0$, and an analytical expression can be obtained for the energy spectrum of the QD:

$$E_{nl} = \frac{\hbar^2 \lambda_{nl}^2}{2mR^2}, \quad (8)$$

where λ_{nl} is the n -th zero of the Bessel function $J_l(x)$.

Parabolic well model

Another model of the confinement potential for the QD, widely used by many authors, is the parabolic potential well model (Chakraborty, 1999; Maksym and Chakraborty, 1990):

$$V_{\text{conf}}(\rho) = \frac{m\omega_0^2 \rho^2}{2}. \quad (9)$$

This model describes a QD created by non-abrupt heterojunctions and one of the reasons for the appearance of the parabolic potential is the diffusion at the interface between the QD and the barrier materials (Barker and O'Reilly, 1999). The parameter ω_0 in Eq. (9) has the dimensionality of frequency (s^{-1}). The main advantage of this model is that it can be solved analytically. The corresponding Schrödinger equation for the QD with the confinement potential (9) coincides with the problem of 2D harmonic oscillator:

$$\left[-\frac{\hbar^2}{2m} \left(\frac{\partial^2}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial}{\partial \rho} + \frac{1}{\rho^2} \frac{\partial^2}{\partial \varphi^2} \right) + \frac{m\omega_0^2 \rho^2}{2} \right] \psi(\rho, \varphi) = E\psi(\rho, \varphi). \quad (10)$$

Fig. 1 First few energy levels of a planar GaAs/Ga_{0.7}Al_{0.3}As QD with square well confining potential vs the radius of the dot.

Due to the circular symmetry of the parabolic confinement potential we again can search the solution of Eq. (10) in the form of (4). As a result for the radial wave function we get

$$\left[-\frac{\hbar^2}{2m} \left(\frac{d^2}{d\rho^2} + \frac{1}{\rho} \frac{d}{d\rho} - \frac{l^2}{\rho^2} \right) + \frac{m\omega_0^2 \rho^2}{2} \right] f(\rho) = E f(\rho). \quad (11)$$

The solution of Eq. (11) can be found in textbooks on quantum mechanics (see e.g., Flügge, 1999). The energy eigenvalues are given by the expression

$$E_{nl} = \hbar\omega_0(2n + |l| + 1), \quad n = 0, 1, 2, \dots, \quad l = 0, \pm 1, \pm 2, \dots, \quad (12)$$

and for the corresponding wave functions we get

$$|n, l\rangle \equiv \psi_{nl}(\rho, \varphi) = \frac{1}{a} \sqrt{\frac{n!}{\pi(n + |l|)!}} \exp\left(-\frac{\rho^2}{2a^2}\right) \left(\frac{\rho}{a}\right)^{|l|} L_n^{|l|}\left(\frac{\rho^2}{a^2}\right) \exp(il\varphi), \quad (13)$$

where $a = \sqrt{\hbar/m\omega_0}$ and $L_n^l(x)$ are the Laguerre polynomials.

In Fig. 2(A) the schematic picture of the energy spectrum of a QD with parabolic confinement potential is presented. The ground state is $|n, l\rangle = |0, 0\rangle$ with the energy $E_{00} = \hbar\omega_0$. All energy levels are equidistant and the separation between neighboring levels is again equal to $\hbar\omega_0$. All states except the ground state are degenerate, and the degeneracy of a state $|n, l\rangle$ is $N = 2n + |l| + 1$. Therefore we can state that the main parameter which describes the entire energy spectrum of parabolic QD is $\hbar\omega_0$. The question now is how to choose the correct value for it using physical parameters of the dot: radius R and the barrier height V_0 . We can estimate ω_0 using, e.g., the condition $m\omega_0^2 R^2/2 = V_0/2$, which will lead to

$$\omega_0 = \sqrt{\frac{V_0}{mR^2}}. \quad (14)$$

As an example in the GaAs/Ga_{0.7}Al_{0.3}As heterostructure, $m = 0.067m_0$, $V_0 = 225$ meV and when the radius of QD $R = 10$ nm we get $\hbar\omega_0 \simeq 50$ meV. In Fig. 2(B) the parabolic confinement potential (solid line) and the square well potential (dashed line) are presented for GaAs/Ga_{0.7}Al_{0.3}As QD of radius 10 nm. Corresponding energy levels for a parabolic QD are also presented.

The effect of non-parabolicity and anisotropy of the confinement potential

Because of the difference of elastic constants, usually an elastic strain field arises between the QD and the surrounding material, which can lead to the breaking of the QD symmetry and hence to the modification of the band structure. For weakening of the strain and stress in such structures one should smoothen the abrupt heterojunction between the QD and the matrix. One of the efficient methods is the post-growth rapid thermal annealing (Agarwal et al., 2013) that induces interdiffusion between the heterojunction materials resulting in the disappearance of the strain field and to the smearing of QD confining potential. Such strain-free QD structures are shown to have better optical quality that makes them excellent candidates in the QD laser and photovoltaic applications (Jo et al., 2011; Wu et al., 2010). While the parabolic potential is reliable for modeling smooth and deep confining potentials, it is not appropriate for description of a finite potential with a smooth profile, especially, when one deals with an array of QDs with a non-vanishing quantum interaction. In such cases the theoretical description of electron dynamics in the QDs becomes possible owing to the application of some model potentials that are widely used in other fields of physics. One of them is the so called Woods-Saxon potential that was first introduced for modeling of the nucleons' interaction in the atomic nucleus (Woods and Saxon, 1954). The modified 2D Woods-Saxon potential which can be used to describe the confinement potential of planar QDs has the following form:

$$V_{\text{conf}}(\rho) = V_0 \left(1 - \frac{1}{1 + \exp\left(\frac{\rho - R}{\alpha}\right)} \right) \quad (15)$$

Fig. 2 (A) Schematic picture of the energy spectra with corresponding quantum states $|n, l\rangle$ of a QD with parabolic confinement potential. (B) Parabolic potential model for GaAs/Ga_{0.7}Al_{0.3}As QD of radius 10 nm with $\hbar\omega_0 = 50$ meV. Dashed line corresponds to the equivalent square well potential.

where ρ is the distance from the QD center, R is the QD radius, V_0 describes the “initial” (for the rectangular well without smearing) depth of the potential and α is the smearing parameter, which describes the characteristic thickness of the heterojunction. It has been shown that one can successfully fit the potential profile formed due to the interdiffusion process by an appropriate choice of the above mentioned parameters as functions of the diffusion length (Aziz Aghchegala et al., 2011; Mughnetsyan and Kirakosyan, 2008). The plot of the modified 2D Woods-Saxon potential in unites of V_0 is presented on Fig. 3(A) for different values of the smearing parameter. It is easy to see that the potential value at $\rho = R$ is the half of the “initial” potential. The rectangular potential profile, which corresponds to $\alpha \rightarrow 0$ is presented as dashed line. The dependence of the electron energies for the several lowest energy levels inside a QD on the Woods-Saxon parameter is presented on Fig. 3(B) for the QD radius $R = 10$ nm and the “initial” height of the potential barrier $V_0 = 228$ meV. The energy values are calculated for the electron effective mass $m = 0.067m_0$, which corresponds to the motion in the GaAs material. As is seen from the figure the effect of smearing is comparatively strong for the energy levels in the middle of the potential well.

The anisotropy effects of a planar QD can be taken into account by a parabolic confinement potential with different ($\omega_1 \neq \omega_2$) frequencies along the x and y axes, which will model an elliptic QD:

$$V_{\text{conf}}(x, y) = \frac{m\omega_1^2 x^2}{2} + \frac{m\omega_2^2 y^2}{2}. \quad (16)$$

For this case the energy spectrum of the QD will be a sum of two 1D harmonic oscillator energies and the wave functions will be the products of two 1D harmonic oscillator eigenfunctions:

$$E_{n_1 n_2} = \hbar\omega_1 \left(n_1 + \frac{1}{2}\right) + \hbar\omega_2 \left(n_2 + \frac{1}{2}\right), \quad (17)$$

$$\psi_{n_1 n_2}(x, y) = C \exp\left(-\frac{x^2}{2a_1^2}\right) \exp\left(-\frac{y^2}{2a_2^2}\right) H_{n_1}\left(\frac{x}{a_1}\right) H_{n_2}\left(\frac{y}{a_2}\right), \quad n_1, n_2 = 1, 2, 3, \dots, \quad (18)$$

where C is the normalization constant, $a_i = \sqrt{\hbar/m\omega_i}$ ($i = 1, 2$) and $H_n(x)$ are the Hermite polynomials. The derivation of Eqs. (17) and (18) can be found in textbooks of quantum mechanics (see e.g., Flügge, 1999).

Quantum dot in a magnetic field: Landau levels vs the Fock-Darwin states

In this section the effect of constant uniform magnetic field on electron states in a planar QD will be discussed. Historically the electron states and the magnetic properties of free electron gas in uniform magnetic field have been studied theoretically by Landau (1930). It was demonstrated that the electron motion in a plane perpendicular to magnetic field induction vector $\mathbf{B}$ is quantized, and equidistant discrete energy levels (so called Landau levels) can be observed. Fock (1928) and Darwin (1931) have studied electron states of a 2D parabolic potential in a magnetic field. Interestingly after 60 years all of these theoretical results have been materialized and experimentally realized in quantum dots (see e.g., Chakraborty, 1999).

Let us consider a planar QD with parabolic confining potential (see Eq. (9)) in a perpendicular magnetic field. The corresponding Schrödinger equation will have the form:

$$\left[\frac{1}{2m} \left(\hat{\mathbf{p}} - \frac{e}{c} \mathbf{A} \right)^2 + \frac{1}{2} m\omega_0^2 \rho^2 \right] \psi(\rho, \varphi) = E\psi(\rho, \varphi), \quad (19)$$

Fig. 3 (A) Woods-Saxon potential for three different values of the smearing parameter α . (B) The dependence of the energies on the parameter α for few lowest states in a planar QD with modified 2D Woods-Saxon confinement potential.

where $\hat{\mathbf{p}}$ is the electron's momentum operator, e is the elementary charge, c is the speed of light, $\mathbf{A}$ is the magnetic field vector potential and ω_0 is the parameter of parabolic confinement potential of QD. For the vector potential we can choose the symmetric gauge $\mathbf{A} = (-By/2, Bx/2, 0)$. It is easy to see that the operator $\hat{\mathbf{p}}$ and the vector potential $\mathbf{A}$ commute, and therefore by substituting the expression for $\mathbf{A}$ into Eq. (19) and after some manipulations we get

$$\left[-\frac{\hbar^2}{2m} \left(\frac{\partial^2}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial}{\partial \rho} + \frac{1}{\rho^2} \frac{\partial^2}{\partial \varphi^2} \right) + \frac{i\hbar\omega_c}{2} \frac{\partial}{\partial \varphi} + \frac{m\omega_c^2 \rho^2}{8} + \frac{m\omega_0^2 \rho^2}{2} \right] \psi(\rho, \varphi) = E\psi(\rho, \varphi), \quad (20)$$

where $\omega_c = eB/mc$ is the cyclotron frequency. Since the magnetic field does not change the circular symmetry of the system we again can search the solution of Eq. (20) in a form

$$\psi(\rho, \varphi) = C \exp(il\varphi) f(\rho), \quad l = 0, \pm 1, \pm 2, \dots \quad (21)$$

By substituting Eq. (21) into Eq. (20) one can obtain an equation for the radial part of the wave function $f(\rho)$:

$$\left[-\frac{\hbar^2}{2m} \left(\frac{\partial^2}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial}{\partial \rho} - \frac{l^2}{\rho^2} \right) + \frac{m\rho^2}{2} \left(\omega_0^2 + \frac{1}{4}\omega_c^2 \right) \right] f(\rho) = \left(E + \frac{1}{2}\hbar\omega_c l \right) f(\rho). \quad (22)$$

Eq. (22) is similar to Eq. (11) if we choose the effective frequency $\Omega = \sqrt{\omega_0^2 + \omega_c^2/4}$ and replace the energy E in Eq. (11) by $E + \hbar\omega_c l/2$. Using the solutions for the 2D harmonic oscillator, given in Eqs. (12) and (13), we can write down expressions for the energy spectrum and wave functions for parabolic QD in magnetic field:

$$E_{nl} = \hbar\Omega(2n + |l| + 1) - \frac{\hbar\omega_c l}{2}, \quad n = 0, 1, 2, \dots, \quad l = 0, \pm 1, \pm 2, \dots, \quad (23)$$

$$|n, l\rangle \equiv \psi_{nl}(\rho, \varphi) = \frac{1}{a} \sqrt{\frac{n!}{\pi(n+|l|)!}} \exp\left(-\frac{\rho^2}{2a^2}\right) \left(\frac{\rho}{a}\right)^{|l|} L_n^{|l|}\left(\frac{\rho^2}{a^2}\right) \exp(il\varphi). \quad (24)$$

In Eq. (24) the parameter $a = \sqrt{\hbar/m\Omega}$ is the effective magnetic length, which, of course, differs from the actual magnetic length $a_B = \sqrt{\hbar/m\omega_c}$.

In Fig. 4(A) the schematic picture of Fock-Darwin energy spectrum for the parabolic QD is presented. At zero magnetic field the spectrum of the 2D harmonic oscillator can be observed with $E_{nl} = \hbar\omega_0(2n + |l| + 1)$. For the case of a strong magnetic field, when $a_B \ll R$ or $\omega_c \gg \omega_0$, the magnetic quantization prevails over the size quantization of the QD and the energy spectra transforms into Landau levels. The first two Landau levels with energies $\hbar\omega_c/2$ and $3\hbar\omega_c/2$ can be seen (dashed lines in Fig. 4(A)). The calculated low-energy levels of the Fock-Darwin diagram are well reproduced in the magnetotunneling experiments of QDs (Chakraborty, 1999; Schmidt, 1997). In Fig. 4(B) the gray-scale contour plot of differential conductance for a QD is presented as a function of the bias voltage and the magnetic field. Some of low-lying Fock-Darwin states and first two Landau levels are clearly visible in the figure. It is quite remarkable how the theoretical results obtained on 1930 are made visible in semiconductor quantum dots.

The effect of QD anisotropy on the Fock-Darwin spectrum has been studied by Madhav and Chakraborty (1994) and later by Avetisyan et al. (2012). Again we can choose the anisotropic confinement potential of the dot in the form of (16). The single-electron Hamiltonian in a magnetic field will have the form:

$$H = \frac{1}{2m} \left(\mathbf{p} - \frac{e}{c} \mathbf{A} \right)^2 + \frac{1}{2} m (\omega_1^2 x^2 + \omega_2^2 y^2). \quad (25)$$

Fig. 4 (A) The Fock-Darwin spectrum for parabolic QD vs magnetic field. (B) Gray-scale plot of differential conductance for a QD as a function of magnetic field and bias voltage (Chakraborty, 1999; Schmidt, 1997). The locations of the two lowest Landau levels are also indicated.

We can introduce here the rotated coordinates and momenta $q_i, p_i (i = 1, 2)$ such that

$$\begin{aligned} x &= q_1 \cos \chi - \chi_2 p_2 \sin \chi, & y &= q_2 \cos \chi - \chi_1 p_1 \sin \chi, \\ p_x &= p_1 \cos \chi + \chi_1 q_2 \sin \chi, & p_y &= p_2 \cos \chi + \chi_1 q_1 \sin \chi, \end{aligned} \quad (26)$$

where

$$\begin{aligned} \chi_1 &= \chi_2^{-1} = -m \left[\frac{1}{2} (\Omega_1^2 + \Omega_2^2) \right]^{1/2}, \\ \tan 2\chi &= \frac{\omega_c [2(\Omega_1^2 + \Omega_2^2)]^{1/2}}{(\Omega_1^2 - \Omega_2^2)}, \quad \Omega_{1,2}^2 = \omega_{1,2}^2 + \frac{1}{4} \omega_c^2. \end{aligned}$$

In terms of rotated operators the transformed Hamiltonian becomes diagonal,

$$H = \frac{1}{2m} \sum_{i=1,2} (\alpha_i^2 p_i^2 + m^2 \beta_i^2 q_i^2), \quad (27)$$

where

$$\begin{aligned} \alpha_1^2 &= \frac{\Omega_1^2 + 3\Omega_2^2 + \Omega_3^2}{2(\Omega_1^2 + \Omega_2^2)}, & \alpha_2^2 &= \frac{3\Omega_1^2 + \Omega_2^2 - \Omega_3^2}{2(\Omega_1^2 + \Omega_2^2)}, \\ \beta_1^2 &= \frac{1}{4} (3\Omega_1^2 + \Omega_2^2 + \Omega_3^2), & \beta_2^2 &= \frac{1}{4} (\Omega_1^2 + 3\Omega_2^2 - \Omega_3^2), \\ \Omega_3^2 &= \left[(\Omega_1^2 - \Omega_2^2)^2 + 2\omega_c^2 (\Omega_1^2 + \Omega_2^2) \right]^{1/2}. \end{aligned}$$

Since the Hamiltonian (27) is a sum of Hamiltonians of two independent harmonic oscillators, the energy eigenvalues of an anisotropic QD in a magnetic field are obtained as

$$E_{n_1, n_2} = \left(n_1 + \frac{1}{2} \right) \hbar \alpha_1 \beta_1 + \left(n_2 + \frac{1}{2} \right) \hbar \alpha_2 \beta_2. \quad (28)$$

In Fig. 5 the energy spectrum of an anisotropic QD is presented against the magnetic field for the value $\hbar\omega_1 = 4\text{meV}$ and for four different values of $\hbar\omega_2$. At zero magnetic field the system behaves like a couple of linear harmonic oscillators in the x and y directions. For large values of magnetic field induction ($\omega_c \gg \omega_1, \omega_2$) the Landau levels form as in the case of isotropic parabolic confinement. When $\omega_1 = \omega_2$ the confining potential is isotropic and parabolic, and the expression (23) can be obtained if $n_1 = n + (|l| - l)/2$ and $n_2 = n + (|l| + l)/2$. When $\omega_1 \simeq \omega_2$, the energy levels are very similar to that of the isotropic case except that the $(2n + |l| + 1)$ -fold degeneracy at $B = 0$ is lifted due to the breaking of the circular symmetry of QD.

Fig. 5 Fock-Darwin spectrum of anisotropic QD for various values of confining potential parameter ω_2 for fixed value of $\hbar\omega_1 = 4\text{ meV}$.

Electron-electron interactions in QDs

Almost 60 years after the pioneering work of Fock (1928) on a single electron in a parabolic confinement potential under external magnetic field, Maksym and Chakraborty (1990) first introduced the electron-electron interaction in that system. The Hamiltonian of the interacting many-electron system in a planar QD with parabolic confinement potential in a magnetic field has the form:

$$\hat{H} = \frac{1}{2m} \sum_{i=1}^{n_e} \left(\hat{\mathbf{p}}_i - \frac{e}{c} \mathbf{A}_i \right)^2 + \frac{1}{2} m \omega_0^2 \sum_{i=1}^{n_e} \rho_i^2 + \frac{1}{2} \sum_{i \neq j} \frac{e^2}{\varepsilon |\mathbf{p}_i - \mathbf{p}_j|}, \quad (29)$$

where n_e is the number of electrons and ε is the dielectric constant of the system. All other notations are already described in section "Quantum dot in a magnetic field: Landau levels vs the Fock-Darwin states." In the case of a QD with only few electrons, the corresponding Schrödinger equation can be solved numerically by the exact diagonalization technique using many-electron basis states of the non-interacting electrons constructed from the single-electron wave functions presented in Eq. (24). Since the wave functions (24) are the eigenfunctions of the single-electron Hamiltonian of a QD, we should calculate here only the matrix elements of the Coulomb interaction term of the Hamiltonian (29). The 2D Coulomb interaction potential of two electrons can be represented in its Fourier transformed form:

$$\begin{aligned} V(\mathbf{p}_1, \mathbf{p}_2) &= \frac{e^2}{\varepsilon |\mathbf{p}_1 - \mathbf{p}_2|} = \frac{e^2}{(2\pi)^2 \varepsilon} \int \frac{2\pi}{|\mathbf{k}|} \exp[i\mathbf{k}(\mathbf{p}_1 - \mathbf{p}_2)] d\mathbf{k} \\ &= \frac{e^2}{2\pi \varepsilon} \int_0^\infty dk \int_0^{2\pi} d\varphi_k \exp[ik\rho_1 \cos(\varphi_k - \varphi_1) - ik\rho_2 \cos(\varphi_k - \varphi_2)]. \end{aligned} \quad (30)$$

The interaction matrix element connecting two electron states $|n_1, l_1\rangle |n_2, l_2\rangle$ and $|n_1', l_1'\rangle |n_2', l_2'\rangle$ will have the form

$$\begin{aligned} M_{n_1', l_1'; n_2', l_2'}^{n_1, l_1; n_2, l_2} &= \int_0^\infty \rho_1 d\rho_1 \int_0^{2\pi} d\varphi_1 \int_0^\infty \rho_2 d\rho_2 \int_0^{2\pi} d\varphi_2 f_{n_1, l_1}(\rho_1) f_{n_2, l_2}(\rho_2) \exp[-i(l_1' \varphi_1 + l_2' \varphi_2)] \times \\ &\quad V(|\mathbf{p}_1 - \mathbf{p}_2|) f_{n_1, l_1}(\rho_1) f_{n_2, l_2}(\rho_2) \exp[i(l_1 \varphi_1 + l_2 \varphi_2)]. \end{aligned} \quad (31)$$

In Eq. (31) $f_{nl}(\rho)$ is the radial part of the single electron wave function taken from Eq. (24):

$$f_{nl}(\rho) = \frac{1}{a} \sqrt{\frac{n!}{\pi(n+|l|)!}} \exp\left(-\frac{\rho^2}{2a^2}\right) \left(\frac{\rho}{a}\right)^{|l|} L_n^{|l|}\left(\frac{\rho^2}{a^2}\right). \quad (32)$$

After the calculation of angular integrals the interaction matrix element will get the form:

$$M_{n_1', l_1'; n_2', l_2'}^{n_1, l_1; n_2, l_2} = \frac{e^2 \pi^2}{\varepsilon} \delta_{l_1 + l_2, l_1' + l_2'} \int_0^\infty I_1(k) I_2(k) dk, \quad (33)$$

where

$$I_i(k) = \int_0^\infty f_{n_i, l_i}(\rho_i) f_{n_i', l_i'}(\rho_i) J_{|l_i - l_i'|}(k \rho_i) \rho_i d\rho_i, \quad i = 1, 2.. \quad (34)$$

The presence of the Kronecker delta symbol in the expression for the interaction matrix element clearly demonstrates that the Coulomb interaction did not change the total angular momentum of the system, i.e., the latter is a conserved quantity. Therefore all states can be classified by a quantum number J which is the sum of single electrons l values. For a given value of the total angular momentum quantum number J all matrix elements can be calculated numerically and the energy spectrum of the interacting system can be obtained after numerical diagonalization of the Hamiltonian matrix created using the many-electron basis states constructed from the single-electron wave functions. The details of numerical calculations can be found in Chakraborty (1999) and Maksym and Chakraborty (1990).

Magic numbers and the Maksym-Chakraborty effect

The energy levels of three and four electron system obtained numerically by Maksym and Chakraborty (1990) for a GaAs QD with parabolic confinement potential with the parameter $\hbar\omega_0 = 4$ meV are shown in Fig. 6. The energy levels are plotted against the total angular momentum quantum number J for various values of the magnetic field. As can be seen in these figures, there are always two sets of broadened levels separated by a gap. In the limit of zero confinement these would be the lowest two Landau levels. The general trend is that the energies increase with J because the single-electron energies increase with l .

Fig. 6 Energy levels as a function of J for three and four electrons in a parabolic quantum dot (Maksym and Chakraborty, 1990).

The main difference between the low- and high-field behaviors is the ground state angular momentum. It should be noted that single-electron contribution increases linearly with J . In contrast, the interaction term decreases because electrons with higher angular momenta move in orbitals with larger radii, thereby decreasing the Coulomb energy. The net result is that the total energy as a function of J has a minimum. At low fields this minimum occurs at the lowest available J , for which all three or four electrons are placed in states with the Fock-Darwin number $N_{FD} = n + (|l| - l)/2 = 0$. For example, at $B = 2\text{ T}$ the ground state of a three-electron QD occurs at $J = 3$ and for the QD with four electrons at $J = 6$. The interaction, however, causes the ground state J to increase with B , and this effect is caused by the interplay of the single-electron energies and the interaction energy.

One very important result here is that the ground state of electrons in a magnetic field occurs only at certain so called magic values of angular momentum which are dependent on the number of electrons:

$$J_{\text{magic}} = \frac{1}{2} n_e(n_e - 1) + j n_e, \quad (35)$$

where j is an integer number. The ground state always occurs at one of these magic values and the competition between the interaction and the confinement determines the optimum J . To summarize, the magic numbers occur because the magnetic field compresses the wave function of the system and increases the Coulomb energy. At certain critical fields the system can reduce the energy by making a transition to a new ground state which has a larger lateral extent and a higher angular momentum. As the magnetic field is increased, we see a series of abrupt changes in the total angular momentum and the system size. The selected values of angular momentum can be explained in terms of the symmetry of the minimum of the combined confinement and interaction potential.

Surprisingly the behavior of the energy levels as a function of the magnetic field described above cannot be observed in the far-infrared (FIR) or transport spectroscopy. It means that the electron-electron interactions described above do not influence the magneto-optical spectra of the QDs at all. The experimental results demonstrate, albeit in a different situation, a variation of the original Kohn theorem (Kohn, 1961). This theorem states that, in a translationally invariant electron gas, the cyclotron resonance is unaffected by electron-electron interactions. It should be noted that the parabolic confinement potential has the unique property that the Hamiltonian can be written as:

$$H = \frac{1}{2M} \left(\mathbf{P} + \frac{Q}{c} \mathbf{A} \right)^2 + \frac{1}{2} M \omega_0^2 R^2 + H_{\text{rel}}, \quad (36)$$

where $Q = en_e$, $M = mn_e$ and $\mathbf{P} = \sum_{i=1}^n \mathbf{p}_i$ are the total electron charge, mass and the center of mass momentum, respectively, and $\mathbf{R} = \sum_{i=1}^n \mathbf{r}_i / n_e$ is the center of mass coordinate of the system. The first two terms in Eq. (36) describe the motion of the center of mass and the last term is a function of only relative coordinates and includes the interaction. Here we should point out that the center of mass energy is identical to the single-electron energy E_n Eq. (23) because of the fact that $e/m = Q/M$. The FIR radiation excites the center of mass, but does not affect the relative motion. This rather fundamental result for quantum dots, first reported by Maksym and Chakraborty (1990) has been called the generalized Kohn theorem or more appropriately, the Maksym-Chakraborty effect.

The interaction effects can only be probed by deliberately engineering the dots so that the center of mass and relative motions are coupled. There have been a few theoretical studies on the effect of non-parabolicity of the confinement potential and consequent coupling of the center of mass and relative motions. Deviations from the parabolic confinement potential were studied first by Gudmundsson and Gerhardt (1991). Pfannkuche and Gerhardt (1991) studied numerically the magneto-optical response to the FIR radiation of quantum dots containing two electrons. In order to study the possible deviations from the parabolic confinement, they added the non-parabolic and anisotropic terms into the confinement potential in a form:

$$U(\mathbf{r}) = \frac{1}{2} m \omega_4^2 (a r^4 + b x^2 \gamma^2),$$

where ω_4 , a and b are constants. They concluded that even small deviations from the strictly parabolic case brings rich structure in the FIR spectra.

Conclusion

To summarize, we have presented here a brief description of the main theoretical approaches for investigation of electronic properties of semiconductor planar quantum dots. The physical conditions, for which the QDs can be considered as planar, are described. Several models of electron confinement potentials of the QDs have been considered in details. Particularly, the 2D square well model and the 2D parabolic well model are discussed. Analytical expressions for the electron energy spectrum and the wave functions are presented. The effect of non-parabolicity of confinement potential is discussed in the framework of the Woods-Saxon potential model. The models of anisotropic planar QDs are also considered using anisotropic parabolic confinement model. We have demonstrated that the planar QDs under the applied external magnetic field are ideal systems for observation of the Fock-Darwin spectrum and the Landau levels. An interesting competition between the two effects: size quantization and magnetic quantization is discussed. The effect of electron-electron interactions on the characteristics of planar QDs also has been considered. It was demonstrated that in planar QDs with many electrons the ground state in a magnetic field occurs only at certain “magic” values of the angular momentum which are dependent on the number of electrons. The magic numbers occur because the magnetic field compresses the wave function of the system and increases the Coulomb energy. Surprisingly this behavior of energy levels as a function of magnetic field cannot be observed in FIR or transport spectroscopy for planar QDs with parabolic confinement. The electron-electron interactions do not influence the magneto-optical spectra of parabolic QDs at all, because the FIR radiation excites the center of mass, but does not affect relative motion of electrons. This fundamental result for planar quantum dots has been called the generalized Kohn theorem or the Maksym-Chakraborty effect. Even small deviations from the strictly parabolic confinement case bring rich structure in the FIR spectra of QDs.

Abstract

Quantum dots (QDs) are semiconductor nanocrystals with nanometer-scale dimensions, and this results in differences in their physical properties from the properties of the corresponding bulk semiconductors. Energy states of quasiparticles (electrons, holes, excitons, phonons, etc.) in QDs are modified due to the quantum confinement effect that leads to the secondary quantization of the energy levels of those quasiparticles. The electron energy states in a QD depend strongly on its size and shape as well on impurities, defects and surface coating. The electron states in QDs determine their optical properties, such as a shift of the absorption edge to high energies, extremely bright, efficient, and size-dependent photoluminescence, which makes QDs extremely important for numerous applications in photonics, optoelectronics and biomedicine. The chapter includes a brief introduction into the preparation methods and properties of different QDs, starting from small semiconductor nanocrystals in solid matrix discovery by Ekimov and Onushchenko in 1981, colloidal QDs, self-organized QDs in semiconductor heterostructures, and perovskite QDs. The first section describes the quantum confinement effect in QDs for different approximations, i.e., so-called “strong confinement regime” (when the Coulomb interaction between optically excited electron and hole is much weaker than the sum of their confinement energies) and “weak confinement” or “excitonic regime” (when the Coulomb interaction between the electron and hole in QDs should be considered). The next sections are devoted to the optical and luminescent properties of QDs, which are covered by the quantum confinement, defects, impurities and surface coating. The last section presents examples of the optoelectronic and biomedical applications of QDs. The main issues related to the physical background and applications of QDs as well the future of research in the field of QD optics are summarized in the conclusion.

Key points

- Spatial confinement leads to the secondary quantization of the energy states of electron, holes and excitons in quantum dots.
- Optical properties of QDs are dependent on their size, shape, impurity content, defect states and surface coating.
- Efficient radiative recombination of excitons in QDs promotes their optoelectronic applications in light emitting diodes and lasers.
- Bright photoluminescence of QDs is used for their applications as luminescent labels in bioimaging.

Introduction

Recent development of the condensed matter physics, material sciences and semiconductor technologies deals with production and investigation of semiconductor nanocrystals with physical and chemical properties, which are promising for various applications. One of the important objects in the physics of nanostructures are quasi-zero-dimensional systems or quantum dots (QDs), which usually represent semiconductor crystals with sizes in all three dimensions from units to tens of nanometers. In most cases, QDs are crystalline nanoparticles (NPs) located in some matrix having the properties of a dielectric or semiconductor with energy electronic spectra, providing potential barriers for charge carriers (electrons and holes) in the QDs.

Among the variety of QDs, there are several main types that are most often studied experimentally and theoretically and are also used in various applications. First, these are nanocrystals of semiconductors dispersed in liquids (colloidal QDs) or embedded in solid-state matrices of glasses, dielectrics or wide-band gap semiconductors, as schematically shown in Fig. 1a. When QDs are grown in a liquid or crystallized in an amorphous dielectric matrix, they usually have a spherical shape (Fig. 1a). It was in such a system, where QDs of copper chloride (CuCl) were crystallized in silicate glass and an effect of the quantum confinement for charge carriers in QDs was discovered in 1981 (Ekimov and Onushchenko, 1981).

Fig. 1 Schematic images of several types of QDs: (a) colloidal or obtained by crystallization in a solid matrix, (b) self-assembled QDs on a solid substrate, and (c) Pe-QDs.

Second important type of QDs are so-called self-assembled ones, which are usually grown by molecular beam or gas-phase epitaxy (Fig. 1b). The main mechanism responsible for the self-assembling of such QDs is the Stranski–Krastanov growth, which is controlled by mechanical stress induced by mismatch between the lattice constant of the substrate and QDs (Stranski and Krastanov, 1938).

So-called perovskite QDs (Pe-QDs), which are nanocrystals of organometallic or inorganic compounds with a perovskite structure, i.e., ABX_3 , where A are B cations and X is an anion. Pe-QDs are usually formed by chemical methods in solutions, are intensively studied now. Such QDs are either spherically or cubically shaped, and they are characterized by intense absorption and photoluminescence, which can be tuned in the visible and near-infrared spectral region, depending on the composition and dimensions of Pe-QDs (Zhou and Wang, 2020).

Quantum confinement effect

The quantum confinement for charge carriers influences the optical properties of semiconductor nanocrystals that becomes significant if their sizes are smaller 10–20 nm. For QDs in the so-called strong confinement mode, the wave functions of quasiparticles experience three-dimensional secondary quantization (Efros and Efros, 1982). In this case the wave functions of electrons and holes in a spherically symmetric well with a radius a and infinitely high walls have the form (Ekimov et al., 1985):

$$\Psi_{n,l,m}(r, \vartheta, \phi) = Y_{l,m}(\vartheta, \phi) \frac{\sqrt{2}}{a\sqrt{r}} \frac{J_{l+1/2}(k_{l,n}r)}{J_{l+3/2}(k_{l,n}a)} \quad (1)$$

where $Y_{l,m}$ are the normalized spherical functions, l is the momentum, m is the momentum projection to a certain direction, J_l is the Bessel function, and $k_{l,n}$ are determined by the following condition:

$$J_{l+1/2}(k_{l,n}a) = 0 \quad (2)$$

where $n = 1, 2, 3, \dots$ is the number of the root of the Bessel function of given $l = 0, 1, 2, \dots$

The energy levels of electrons and holes can be expressed by the following equation:

$$E_{l,n}^{e,h} = \frac{\hbar^2 \phi_{l,n}^2}{2m_{e,h}^* a^2} \quad (3)$$

where m_e^* and m_h^* are the effective masses of electrons and holes, respectively, which are assumed to be constant independently on the size of QD.

Thus, the optical forbidden gap of QD is given as follows:

$$E_g^{QD} = E_g + \frac{\hbar^2 \pi^2}{2\mu a^2} \hbar v_{01} = E_g + \frac{\hbar^2}{8\mu a^2} \quad (4)$$

where E_g and E_g^{QD} is the optical forbidden gap of the bulk semiconductor and QD, respectively, $\mu = m_e^* m_h^* / (m_e^* + m_h^*)$ is the reduced mass of the charge carriers.

Fig. 2 schematically shows the transformation of the quasi-continuous energy spectra of electron and holes in a bulk semiconductor to the discrete energy levels in the corresponding QD that is described by Eqs. (3) and (4). Note, the above mentioned analysis with Eq. (4) are valid in the case of so-called “strong confinement regime” when the Coulomb interaction between optically excited electron and hole is much weaker than the sum of their confinement energies given by Eq. (3). This regime is realized when the QD’s radius is much smaller than the exciton radius, i.e., $a \ll r_{ex} \hbar v_{01} = E_g + \frac{\hbar^2}{8\mu a^2}$ (Ekimov et al., 1985).

For the case of $a \gg r_{ex} \hbar v_{01} = E_g + \frac{\hbar^2}{8\mu a^2}$ it is realized so-called “weak confinement” or “excitonic regime” and one should consider the Coulomb interaction between the electron and hole in QDs. It results in the following expression for the optical absorption threshold (Ekimov et al., 1985):

Fig. 2 Schematic of the transformation of the quasi-continuum energy dispersion curves for electrons and holes in a bulk semiconductor (3D) toward discrete energy states in a QD.

$$h\nu_0 = E_g - E_{ex} + \frac{\hbar^2 \pi^2}{2Ma^2} \quad h\nu_{01} = E_g + \frac{\hbar^2}{8\mu a^2} \quad (5)$$

where E_{ex} and $M = m_e^* + m_h^*$ are the binding energy (exciton Rydberg energy) and total mass of the exciton, respectively.

When the dielectric constant of a QD is larger the corresponding value of surrounding medium, the electron–hole interaction and consequently the binding energy and oscillator transition strength increase in the QD (Brus, 1984). This effect is also known as the dielectric confinement for excitons in QDs (Efros and Brus, 2021; Alivisatos, 1996). Indeed, for both colloidal QDs and those embedded in a glass or other isolating solid matrices the real part of the QD’ dielectric function of in the optical range is usually larger the corresponding value of the matrix and it reduces the electric field of light due to so-called local field effect and reduces the exciton-photon coupling in the QD. Furthermore, the polarization properties of colloidal QDs as well as of their randomly oriented ensembles are determined both by the anisotropy of the local field effect and by the symmetry of the exciton states participating in the optical transitions. Therefore, the dielectric confinement changes the Coulomb interaction in an exciton in a QD and it also influences the eigen energies of electron or hole inside the QD. The latter effect can be described as an interaction between the electron (hole) with its own image charge outside of the QD (Rodina and Efros, 2016).

Optical absorption

The change in electronic states of QDs due to the quantum confinement obviously leads to a modification of their optical properties, e.g., to the high-energy shift of the absorption edge. This “blue” shift can be described by Eqs. (4) and (5) for the strong and weak confinement, respectively. The “blue” shift of the optical absorption edge in QDs crystallized in a glass matrix was unambiguously demonstrated by Ekimov and Onushchenko (1981). While it is usually difficult to obtain the absorption spectrum of a single QD in the experiment, many such QDs with some size distribution participate in the formation of the absorption spectrum.

Fig. 3 shows absorption spectra of CuCl, CuBr and CdS QDs with different mean sizes measured at low temperature. The absorption edge for all the samples exhibits a shift in high photon energy region that is well explained by the quantum confinement model. However, the spectra of CuCl and CuBr CDs consist of only two broad peaks, whose relative spectral positions cannot be described by Eqs. (4) and (5). The most relevant explanation of these two peaks is based on considering a contribution from sub-bands of the valence bands of the corresponding semiconductors. Since the Bohr radius of an exciton in the bulk CuCl is about 0.7 nm, the corresponding QDs with sizes above 2 nm should be described by the model of weak confinement (Eq. (5)). The absence of excitonic peaks with different quantum number is explained by inhomogeneous broadening of the absorption spectrum due the size distribution of QDs (Ekimov, 1991; Efros and Brus, 2021).

For a detailed description of the optical properties of QDs, it is important to know how their electronic spectrum changes when the size of nanocrystals changes. Fig. 4 shows a transmission electron microscopy (TEM) image, schematic view of the atomic structure and optical transition diagram for an individual colloidal CdSe (Efros and Brus, 2021). However, the heterogeneous distribution of QDs in size and shape observed in the experimental samples as glasses of liquids with a QD ensemble complicates an identification of the optical transitions in the latter. Therefore, methods such as differential absorption spectroscopy, also known as the “pump-sensing” method and PL excitation spectroscopy, are used in the study of the electronic spectrum of QD. Historically, the most widely used method is the differential absorption spectroscopy (Norris et al., 1994; Norris and Bawendi, 1996). However, the photoinduced absorption complicates the interpretation of the obtained spectral features due to influences of the carrier recombination and optical gain (Klimov, 2003). The most detailed information can be provided by PL excitation spectroscopy (Ekimov, 1991).

Fig. 3 Absorption spectra of different QDs in glass matrices at low temperature ($T = 4.2$ K): (a) CuCl with $a = 31$ nm (curve 1), 2.9 nm (curve 2), and 2.0 nm (curve 3); (b) CuBr with $a = 24$ nm (curve 1), 3.6 nm (curve 2), and 2.3 nm (curve 3); (c) CdS with $a = 33$ nm (curve 1), 2.3 nm (curve 2), 1.5 nm (curve 3), and 1.2 nm (curve 4). Indeed, when a sample containing QDs is illuminated by light with photon energy much higher than the energy of the lower optical transition, the entire ensemble of QDs in the sample is excited. As a result, there is a wide peak (width at half the height FWHM > 0.05 eV) of the PL (see Fig. 5a). At the same time, when removing the excitation spectra of PL, a narrow spectral luminescence band is selected, and the photon energy of the exciting light is scanned. As a result, the inhomogeneous broadening of the spectrum is significantly reduced (Norris and Bawendi, 1996).

Fig. 5 (a) Absorption spectrum (solid curve) and PL (dotted curve) of CdSe QDs with an average radius of ~ 28 Å; (b) PL excitation spectrum of the same sample; (c) normalized PL excitation spectra for samples with seven different QD sizes in the range from ~ 15 to ~ 43 Å. All measurements at $T = 10$ K. Reproduced with permission from Norris DJ, Bawendi MG (1996) Measurement and assignment of the size-dependent optical spectrum in CdSe quantum dots. *Physical Review B* 53: 16338–16346.

As can be seen from Fig. 4, optical transitions that overlap in the absorption spectrum [Fig. 5a], become clearly resolved in the excitation spectrum of PL [Fig. 5b]. Analyzing the PL excitation spectrum of samples with different mean sizes [Fig. 5c], one can select a set of transitions in it. The dependence of the energy of the first excited states, i.e., $1S_h1S_e$, predicted by the simple effective mass model described above is approximately proportional to $1/a^2$ in a wide range of sizes as shown in Fig. 6 for CdSe QDs. However, in many cases, along with the position of the first excited state $1S_{3/2}1S_e$ it is important to know the positions of higher states, such as $2S_{3/2}1S_e$ и $1P_{3/2}1P_e$. Fig. 7 demonstrates that for the certain range of the QD radius the size dependences of the optical transitions in QDs of CuCl and CdS can be also fitted with the function proportional to $1/a^2$ in the agreement with Eqs. (4) and (5) (Efros and Brus, 2021).

Fig. 7 (a) Dependences of the energy of the two exciton lines (Z_3 and $Z_{1,2}$) in CuCl QDs on the square of reciprocal radius. (b) Dependences of the three lowest optical transitions on the square of reciprocal radius for CdS QDs. Symbols are experimental data connected by the red lines to guide the eye. The initial slopes of the experimental dependence are shown by black straight lines. Reproduced with permission from Efros AIL, Brus LE (2021) Nanocrystal quantum dots: From discovery to modern development. *ACS Nano* 15: 6192–6210.

To accurately describe the dependence of excited states on the size of nanocrystals, it is necessary to take into account the spin-orbital interaction leading to the splitting of the valence band into subzones of heavy holes, light holes and spin-split subzones, as well as the infinite height of potential barriers, Coulomb interaction and nonparabolicity of the conduction band (Norris and Bawendi, 1996). Thus, the deviation of the theoretical curve from the experimental data at large values of the QD radius (see Figs. 6 and 7) is apparently associated with an increase in the role of the Coulomb interaction with the weakening of the confinement. While the discrepancy between theoretical and experimental data at small values of the nanocrystal size is associated either with a violation of the effective mass model, or with the finite value of the potential barrier at the boundary between QD and surrounding medium (Efros and Brus, 2021).

The heterogeneous broadening plays an important role in explaining a number of physical properties of real samples of QDs. A monotonic dependence of the position of the PL spectrum on the photon energy of exciting light was found and explained by the size distribution of QDs, taking into account the dependence of the energy of the electron and hole levels on the size of QDs and the removal of the degeneracy of the hole levels (Rodrigues et al., 1995). Due to the complex structure of the valence band of CdSe QD, the predominant absorption of the same photon can go through transitions $1P_{3/2} \rightarrow 1P_e$ or $1P_{1/2} \rightarrow 1P_e$ nanocrystals of different sizes, while exciton recombination in both cases will go through the transition $1S_e \rightarrow 1S_{3/2}$ (Ekimov et al., 1993).

Photoluminescence

The photoluminescence (PL) of QDs is their most interesting property with a number of various practical applications. Let us consider for example colloidal CdSe QDs those intensive studies were facilitated by the relative simplicity of their production and the ability to accurately control the size and shape of nanocrystals. The most common way to obtain CdSe QDs is colloidal synthesis from a solution, which results in QD suspensions of a given radius. The Bohr exciton radius in CdSe is about 5.6 nm (Efros and Brus, 2021). This means that it becomes possible to observe the quantum confinement via the “blue” shift of the PL spectrum with a decrease in the size of QDs as shown in Fig. 8. The obtained PL line is attributed to the radiative recombination of excitons in such QD. When the QD’s radius changes from 1.35 to 2.4 nm it is accompanied by a shift of the maximum of PL spectrum from 510 to 610 nm [17], as can be seen from Fig. 18. For optoelectronic and biophotonic applications of QDs, a high quantum yield (QY) of the luminescence is very important. The QY value in a QD usually increases due to the spatial confinement of excitons. However, two factors, which are insignificant in the bulk crystal, may reduce the radiative recombination rate in QDs. One of them is the nonradiative recombination on surface defects. Indeed, QDs with radius of about 1–2 nm consist of about 1/3 of the atoms on their surfaces, and the radiative recombination dominates only in QDs with surfaces, which are well passivated by the corresponding chemical groups and compounds (Medenitz et al., 2005).

Because of the small volume of a QD, defects of the crystal lattice, which can exist in the bulk material, do not usually present in the former. At high optical excitation, the nonradiative Auger recombination processes are stronger in nanocrystals than in the bulk material. Under intense excitation, when the formation of more than one exciton is possible, the local concentration of electron-hole pairs in the nanocrystal, due to the geometric restriction can be very large of the order of 10^{18} – 10^{20} cm⁻³. In addition, the spatial localization leads to a break-down the quasi-momentum conservation rule, and the probability of Auger process increases (Ekimov, 1991). Another process that reduces the quantum yield of exciton PL is nonradiative recombination on surface defects. When the QD’ radius $a \approx 1.5$ nm, about 1/3 of the QD’ atoms are on the surface, and the radiative recombination dominates only in QDs with well passivated surfaces by the corresponding chemical groups or compounds (Efros and Brus, 2021).

The intrinsic PL of CdSe QDs with diameters from 1.7 to 6.3 nm, coated with an organic shell, was investigated in a wide temperature range from 1.3 to 300 K and the results revealed nonmonotonic temperature dependences. Fig. 9 shows an example of the temperature dependence for the spectrally integrated PL intensity of CdSe QDs with $d = 4.3$ nm, while similar dependences took places for all diameters of the studied QDs (de Donegá et al., 2006).

Fig. 8 Absorption (ABS) and emission (EM) spectra of CdSe QDs with different sizes indicated below in the panel nearby the corresponding PL images obtained under excitation at 365 nm. Reproduced with permission from Medenitz IL, Tetsuoyeda H, Goldman ER, Mattousi H (2005) Quantum dots bioconjugates for imaging, labelling and sensing. *Nature Materials* 4: 435–446.

Fig. 9 Dependence of the integral PL intensity of CdSe QDs with $d = 4.3$ nm on temperature, where region I is the radiative mode, region II is the “attenuation” mode, and region III is the “anti-attenuation” mode. Reproduced with permission from de Donegá CM, Bode M, Meijering A (2006) Size- and temperature-dependence of exciton lifetimes in CdSe quantum dots. *Physical Review B* 74: 085320.

The temperature dependence of the exciton PL intensity of CdSe QDs can be better understood by considering simultaneously the PL lifetimes at different temperatures. Fig. 10 shows PL transients of CdSe QDs with mean diameters of 1.7 and 4.3 nm measured at temperatures varied from 1.3 to 300 K. Fig. 11 shows dependences of the exciton PL lifetime on temperature for all studied samples. An analysis of the decay curves and integral intensities allows us to distinguish three temperature regimes of the exciton PL (de Donegá et al., 2006). The low-temperature regime (from 1.3 to 50 K) is characterized by an approximately constant QY that indicates the dominating role of the radiative recombination (“radiative regime” I in Fig. 9). At temperature 1.3 K the PL decay curves are bi-exponential for all QD sizes (Fig. 10). The fast component of the bi-exponential decay corresponds to the recombination from the bright exciton level preceding thermalization between the lower (dark exciton) and upper (bright exciton) levels. As the temperature increases, the fast component gradually disappears, while the slow component becomes faster, until the monoexponential character of the PL decay at $T \sim 10$ K is established. In the case of bi-exponential decay the lifetimes for the slow component are shown in Fig. 10. The PL transient curves remain monoexponential, and the rate of decay increases significantly

Fig. 10 PL transients of CdSe QDs with $d = 4.3$ nm (a) and $d = 1.7$ nm (b) at different temperatures indicated near the corresponding curves ($\lambda_{\text{ex}} = 406$ nm, $\lambda_{\text{PL}} = 609$ nm and 483 nm for $d = 4.3$ nm and 1.7 nm, respectively). Fig. 11 Dependence of the exciton lifetimes for CdSe QDs with diameters from 1.7 to 6.3 nm. The results for the core/shell system (CdSe/ZnSe/ZnS) are also presented. The temperature scale is logarithmic. In the insert, the area is above 200 K (linear scale) for a sample with a diameter of 4.3 nm. Reproduced with permission from de Donegá CM, Bode M, Meijering A (2006) Size- and temperature-dependence of exciton lifetimes in CdSe quantum dots. *Physical Review B* 74: 085320.

with an increase in temperature to ~ 50 K, when the intensity of PL begins to decrease. Above 50 K, the PL decay becomes even more rapid and non-exponential, which indicates the thermal activation of electron capture on traps and non-radiative recombination ("attenuation mode" II in Fig. 9). The lifetimes determined from the exponential tails of the PL decay curves correspond to the radiative recombination of excitons and remain approximately constant at temperatures above ~ 50 K. It turns out that the beginning of the attenuation mode does not depend on the size of QDs or surface passivation. At temperatures above ~ 250 K, the intensity of PL begins to recover, while the lifetimes begin to increase, and the PL decay becomes almost monoexponential at room temperature as it was found in the experiment by de Donegá et al. (2006).

The most significant temperature and size dependence of the exciton PL in CdSe QDs is observed at temperatures below ~ 50 K, implying that the exciton lifetimes themselves change (Fig. 11). The dependence of the exciton lifetime on temperature in the radiative mode (mode I) can be modeled by a three-level system assuming thermal equilibrium between two radiating levels, the lower of which gives longer lifetimes (dark exciton) than the higher (bright exciton), and it can be described by the following equation (de Donegá et al., 2006):

$$\frac{1}{\tau} = \frac{1}{\tau_{\text{dark}}} \left(\frac{e^{\Delta E/KT}}{1 + e^{\Delta E/KT}} \right) + \frac{1}{\tau_{\text{bright}}} \left(\frac{1}{1 + e^{\Delta E/KT}} \right), \quad (6)$$

where τ is the measured PL lifetime, τ_{dark} and τ_{bright} are the lifetimes of dark and bright excitons, respectively, ΔE is the spitting energy between these two exciton levels. Despite its simplicity, such a model well describes the experimentally observed temperature dependence of the PL lifetime of CdSe QDs shown in Fig. 12 from the work of de Donegá et al. (2006).

Fig. 12 Temperature dependence of the exciton lifetime of CdSe QDs with mean diameter 2 nm (black circles) and its approximation (red lines) by Eq. (6) with $\tau_{\text{dark}} = 1235$ ns, $\tau_{\text{bright}} = 40$ ns, and $\Delta E = 1.39$ meV. Effects of shells and impurities

Semiconductor heterostructures, such as core/shell QDs, exhibit different optical properties depending on the spatial localization of charge carriers after photoexcitation (type I or type II), which can be controlled by changing the ratio of the diameter of the central part (core) of QD and the thickness of its shell (Chin et al., 2007). In type I QDs, electrons and holes are concentrated in the same part of the heterostructure, while in type II QDs, electrons and holes are separated in space, which leads to the formation of an indirect exciton. A consequence of the radiative recombination of an indirect exciton is a photon with an energy lower than the energy of the band gap of both the shell material and the nucleus. This makes it possible to achieve wavelengths larger than the wavelengths of single-component QDs or type I QDs (Ekimov, 1991; Ekimov et al., 1993; Klimov, 2003).

Fig. 13 shows spectra of the absorption and PL of CdTe/CdSe colloidal heteronanocrystals with a 2.6 nm diameter CdTe core and increasing shell thickness and the corresponding PL transients are shown in Fig. 14 (Chin et al., 2007). The PL spectrum and exciton lifetime are found to change dramatically during the growth of the shell of CdTe/CdSe heteronanocrystals. The maximum of PL spectra shifts from 535 nm (2.32 eV) for CdTe nuclei to 770 nm (1.61 eV) for sample E. The absorption spectra also experience redshift, but as the CdSe shell grows, the absorption spectra blur, and the oscillator strength at the emission wavelength decreases, while the exciton lifetimes become longer (Chin et al., 2007).

Increasing the CdSe shell results in an increase in the exciton lifetime and a multi-exponential decay in CdTe/CdSe QDs as shown in Fig. 14. These observations are explained by a decrease in the rate of nonradiative recombination, since it is accompanied by a significant increase in the quantum yield from 7% to 46% (Chin et al., 2007). A further increase in the thickness of the shell leads to an even greater increase in the exciton lifetime and to a transition from mono- to bi-exponential decays. The fast component of the bi-exponential decay refers to CdTe/CdSe heteronanocrystals, in which nonradiative recombination of excitons plays an essential role, while the slow component is attributed to purely radiative decay. Thus, the results obtained in this work indicate that as the thickness of the heteronanocrystal shell increases, the overlap integral of the electron and hole wave functions decreases rapidly (Chin et al., 2007).

Besides the effect of shell, the PL properties of QDs are also influenced by impurities and defect in the QD lattice. The latter effect was observed for the copper impurities in CdSe QDs (Meulenberg et al., 2004; Tananaev et al., 2009). Fig. 15a shows PL spectra of $\text{Cd}_{1-x}\text{Cu}_x\text{Se}$ QDs compared with undoped ones (Meulenberg et al., 2004). The PL spectrum of the undoped sample consists of a narrow peak of interband recombination of excitons in CdSe QDs with a maximum at a photon energy of 2.15 eV and a wide peak in the low-energy part of the spectrum, the nature of which is associated with surface defects in CdSe. It can be seen from the figure that the introduction of copper into the QD structure leads to the quenching of the exciton PL and the appearance of an intense luminescence band in the low-energy region, which experiences a red shift with an increase in the copper content in the sample. The observed effect can be explained by the fact that the Cu_4 cluster formed when introduced into the CdSe lattice leads to the appearance of structural defects and, accordingly, deep energy levels lying lower than the energy levels of surface defects of unalloyed QDs. Charge carriers are captured at these levels. With an increase in the concentration of copper, most of the photogenerated charge carriers are captured at defect-related energy levels followed with the IR PL emission (Meulenberg et al., 2004).

An effect of the doping on both the shape and PL properties of Cd(Cu)Se QDs was found by Tananaev et al. (2009). The samples of Cd(Cu)Se QDs were obtained by introducing copper precursors as copper stearate or triphenylphosphine complex tetraiodidetratedi $[\text{Cu}_4\text{I}_4](\text{Ph}_3\text{P})_4$. The size of the synthesized nanocrystals varied from 2 to 5 nm and the shape for QDs synthesized with copper stearate was predominantly spherical (see Fig. 16a). According to the chemical analysis, the average copper content in Cd(Cu)Se QDs was varied from 0.03 to 1 at.% (Tananaev et al., 2009).

The introduction of a large amount of copper about 1% into CdSe QDs leads to a change in the shape of growing nanocrystals, i.e., from spheres they turn into tetrapods (Fig. 16b), which is an excellent illustration of the influence of impurity atoms on the growth of QDs. Thus, using [Cu4I4](Ph3P)4 clusters, it is possible to obtain Cd(Cu)Se QDs in the form of tetrapods. The introduction of an excessively large amount of copper leads to the quenching of the exciton luminescence and the shift of the absorption edge and PL band to the “red” spectral region as shown in Fig. 17 (Tananaev et al., 2009).

The introduction of impurity atoms into the structure of QDs makes it possible to further modify their basic properties and give them new ones rather different from those for undoped QDs that further expands their possible applications. For example, the above mentioned Cd(Cu)Se QDs exhibit PL bands in the near IR region (Meulenberg et al., 2004; Tananaev et al., 2009), which corresponds to the first transparency window of biotissue from ~700 to 1000 nm (Golovynskyi et al., 2018). The PL lifetime of Cd(Cu)Se QDs in the near-IR range was found to be about several microseconds (Tselikov et al., 2011) and it is especially useful for bioimaging applications to improve the luminescent contrast of QDs since the autofluorescence lifetime of biotissue corresponds typically to the nanosecond range (Gu et al., 2013).

Besides the above discussed compound QDs, pure silicon (Si) nanocrystals with silicon oxide or hydride shells as well as nanoparticles, which consist of Si QDs, can also emit efficient room temperature PL in the visible and near-IR spectral regions (Cullis et al., 1997; Mangolini et al., 2005; Erogbogbo et al., 2008; Park et al., 2009; Sugimoto et al., 2013; Gu et al., 2013). While Si QDs usually exhibit weaker and less stable PL than convenient A²B⁶ QDs, ligand-coated Si nanocrystals can possess a high internal QY near unity (Sangghaleh et al., 2015).

Among different physical, chemical and electro- and plasma-chemical methods of the Si nanocrystal synthesis, a method of the laser ablation of a crystalline Si target in inert gas atmosphere is used to prepare water-dispersible highly luminescent nanoparticles, which consist of Si QDs coated with silicon suboxide shells (Gongalsky et al., 2016). The bright and long-lived exciton PL at 600–900 nm and oxide shell related fast PL at 300–500 nm are detectable both in as-prepared laser-ablated films and in aqueous suspensions (Fig. 18). The near-IR band centered at 1.5 eV is explained by the radiative recombination of excitons confined in Si QD' core with diameter of 2–3 nm, while a band centered at 2.7 eV is related to the radiative transitions in the oxide shell of Si QDs (Gongalsky et al., 2016).

A remarkable property of Si QDs is relatively long PL lifetime, which is in the microsecond range and about several milliseconds at room and cryogenic temperature, respectively (Calcott et al., 1993). The long lifetimes of PL in Si QDs are explained by the spin-dependent splitting of exciton states into energetically higher singlet and lower triplet ones (Kovalev et al., 1999) that is similar to the above discussed model of “bright” and “dark” exciton in CdS QDs (de Donegá et al., 2006). The spin-dependent exciton processes in Si QDs and nanoparticles are very important for both their photonic properties (Joo et al., 2015) and biomedical applications, e.g., photosensitization of the singlet oxygen generation for the photodynamic therapy of cancer (Fomin and Timoshenko, 2020).

During last years, Pe-QDs, which represent metal-organic and inorganic lead halide perovskite nanocrystals are attracting the significant attention because of the simplicity of preparation and bright PL with QY exceeding 90% (Zhou and Wang, 2020). The PL band of Pe-QDs is narrow and it can be spectrally tunable by both halide composition, dimensionality, and quantum confinement (Fig. 19). While Pe-QDs are not stable against water and oxygen, their preparation methods are cheap, flexible and well combined with semiconductor optoelectronic technology. The excellent luminescent properties of Pe-QDs make then a promising candidate for new generation of QDs-based LEDs (Li et al., 2019) and lasers (Park et al., 2021).

Optoelectronic and biomedical applications

Specially designed QDs are characterized by PL emission with a high QY and spectral position, which can be tailored in the visible and near-IR regions, that is useful for various biophotonic applications. It is known that one of the directions of biomedical diagnostics is based on fluorescent labeling, for which organic dyes are usually used. However, the photophysical properties inherent in organic dyes, in particular, wide absorption/emission peaks and a low photobleaching threshold, limit the effectiveness of their use in long-term image formation and in the instantaneous detection of a multi-frequency signal. Therefore, QDs are of interest for biophotonics because their high PL QY, a large molar extinction coefficient (10–100 times greater than that of organic dyes), wide absorption with a narrow symmetrical (FWHM ~25–40 nm) PL peak, a large effective Stokes shift, high resistance to photobleaching and exceptionally high resistance to photo- and chemical degradation (Wu et al., 2003; Michalet et al., 2005; de Donegá et al., 2006).

Fig. 20a shows typical PL images of QD-colored living cells explaining the resistance of QDs to photobleaching and Fig. 20b shows a pseudo-color image, which corresponds to the 5-color coloration of the human epithelial cell incubated with QDs (de Donegá et al., 2006). While the PL imaging clearly demonstrates the wide biophotonic potential of QDs based on both the II–VI group compounds (Medenitz et al., 2005; Michalet et al., 2005; Kim et al., 2022) and IV-group semiconductors (Erogbo et al., 2008; Botsoa et al., 2008; Serdiuk et al., 2013; Gu et al., 2013; Gongalsky et al., 2016), it can be also significantly extended by using nonlinear optical bioimaging modalities as second harmonic generation and two photon excited luminescence (Kharin et al., 2019).

QDs prepared from pure Si (Erogbogbo et al., 2008; Gu et al., 2013; Gongalsky et al., 2016) and silicon carbide (Botsoa et al., 2008; Serdiuk et al., 2013) are attractive for bioimaging because they are significantly less toxic than the II–VI group QDs (Medenitz et al., 2005; Yildirim et al., 2011). Moreover, Si QDs and NPs are biodegradable that results in formation of nontoxic silicic acid (Park et al., 2009).

The PL lifetime of Si QDs at room temperature is typically of the order of microseconds (Kovalev et al., 1999; Gu et al., 2013; Gongalsky et al., 2016) and it is significantly longer than the nanosecond lifetimes of autofluorescence of biomolecules in cells and tissues (Golovynskyi et al., 2018). This property of Si QDs can be utilized through the time-gated PL imaging for better discrimination of the QD' PL from the endogenous fluorescence signal that can result in more than 100-fold contrast improvements relative to steady-state imaging (Gu et al., 2013).

Optoelectronic applications of QDs as active media for LED and electrically pumped lasers are based on high QY and temperature stability of their light-emitting properties. Fig. 21 shows a schematic image of the QD laser, which is based on the direct injection of charge carriers into QDs, as a result of which the depletion of non-basic charge carriers occurs in areas outside the QDs. Thus, the non-radiative recombination of charge carriers in these regions, mainly responsible for temperature dependence, can be suppressed (Asryan and Luryi, 2001).

Self-assembled QDs (see Fig. 1b) based on A^3B^5 semiconductors can be employed in creation of compact solid-state lasers (Liu et al., 2005, 2011). Such lasers based on multilayered structures of self-assembled InAs/GaAs QDs (Fig. 22 A) incorporated in quantum wells (QW), i.e., dot-in-a-well (DWELL) structures, together with cladding and contacting layers were epitaxially grown on c-Si substrates (Lee et al., 2012) as shown in Fig. 22b. These structures were able to emit at about 1.3 μm both in the pulsed and continuous-wave (CW) regimes at room temperature (Fig. 22c). Such NIR InAs/GaAs QD lasers being integrated on Ge/Si substrates can be used to realize the long-dreamed of integrated III-V/Si optoelectronics (Lee et al., 2012; Kwoen et al., 2019).

The physical and chemical properties of Pe-QDs together with the simplicity of their preparation if compared to III–V QDs facilitate a wide range of applications of the former in optoelectronics (Li et al., 2019; Zhou and Wang, 2020). Chemical synthesis from liquids is usually used to form metal-organic and inorganic Pe-QDs of high crystal quality and PL QY near unity. The external quantum efficiency (EQE) of the best samples of Pe-QD LEDs has been reported to be about 10–20% (Li et al., 2019). Despite the impressive progress in Pe-QDs LEDs (Zhou and Wang, 2020; Liu et al., 2021, 2022) and lasers (Park et al., 2021) in recent years, their commercial applications remain a challenge. The efficiency and stability of Pe-QDs devices require further improvements to compete with traditional LEDs and fully organic ones.

Conclusion

Different types of QDs as semiconductor nanocrystals crystallized in a solid matrix, colloidal QDs, self-organized semiconductor nanocrystals in heterostructures, metal-organic and inorganic perovskite QDs represent examples of the zero-dimensional solid state systems with unique physical properties. The optical absorption and photoluminescence of QDs are explained by considering the quantum confinement of charge carriers (electron and holes) and electron-hole pairs (excitons) in semiconductor nanocrystals. The energy spectrum and optical properties of QDs are controlled by their chemical composition, spatially confined and localized electronic states, as well as by incorporated impurities and surface coatings. The modern chemical synthesis and semiconductor technology allow tailoring the optical properties of QDs for various applications as light-emitting structures in optoelectronics and luminescent markers in biophotonics.

Abstract

An overview of the electronic and optical properties of the various types of quantum dots (QD) made of solid-state materials is presented. Whereas they share common physical characteristics such as small sizes and the ability to contain and manipulate few particles, QD's exhibit fundamental specificity in the manifestation of electron charge, spin, or single photon emission, each with their respective potential technological applications. In this context, five types of solid state QD's i.e. Planar QD's, Vertical QD's, Self-Assembled QD's, Silicon Nanocrystals, and Colloidal QD's are addressed with their own physical properties. Comprehensive modeling techniques suited for each type of QD are briefly mentioned.

Key points

- Types of Quantum Dots/Fabrications
- Coulomb Blockade and Single Electronics
- Artificial Atoms and Molecules/Entanglement and Quantum Gates
- Optical Emission from Self-Assembled Dots and Colloidal Dots
- Quantum Dot Modeling and Simulation

Introduction

Quantum dots (QD) are nanostructures containing few conduction band electrons or valence band holes, or both bound into excitons. These particles, of which the number ranges between a handful to a few thousand are confined into a quantum box isolated from their environment, either electrostatically or structurally, except from a small channel that controls the access of electrons to the QD. In solid state structures, mostly in semiconductors, one distinguishes among planar QDs, vertical QDs, or self-assembled QDs, depending upon their fabrication techniques and design with their sizes varying between tens to hundreds of nanometers. QDs with feature size comparable to or smaller than the particle (electrons or holes) Fermi wavelength manifest quantum mechanical properties with energy spectra similar to natural atoms. For this reason, they are often called "*artificial atoms*." In coupled QDs or "*artificial molecules*" particle (electrons or holes) behavior are governed by Coulomb and exchange interactions that can be tuned locally by design or external electric/magnetic fields. Asides from their fundamental interest in realizing tunable

atomic and molecular entities with solid state materials at larger scale than natural atoms and molecules, QDs offer ranges of applications in *single electronics* for memory applications, *spintronics* for quantum computing, *lasers*, *detectors* or *single photon* sources for material characterization or quantum information processing.

Overview

Planar quantum dots

Planar (P) QDs are fabricated by patterning several Schottky metal gates above the surface of a two-dimensional electron gas (2DEG), which isolates electrostatically a few charge carriers in a small region, forming the dot. In Fig. 1 (upper left) the 2DEG is formed at the interface between an undoped GaAs and AlGaAs layer. A thin heavily doped n^+ GaAs cap layer (yellow) is grown on top of the AlGaAs to pin the Fermi level just below the conduction band edge (Meirav et al., 1990). Lateral confinement is achieved by the top metal gates (black) that consists of two slits to enable the electrons to flow from and to the 2DEG through electrostatic barriers of which the height is electrically controlled by the two metal gates. In practice, these electrostatic barriers are weak (a few meVs) and thick (~ 100 nm), which makes the PQD sensitive to external electric perturbation. Charge control in the PQD's is achieved by varying a back gate voltage.

Vertical quantum dots

In vertical (V) QDs, charge carriers are vertically confined between a double resonant tunneling barrier made of hetero-structure layers e.g. InGaAs/AlGaAs/GaAs, while the lateral confinement is achieved by deep mesa etching. In addition, a Schottky metal gate is wrapped around the mesa to electro statically control the number of electrons between the two tunneling barriers (Fig. 1 upper, right) (Kouwenhoven et al., 2001). Electrical contacts are made on the top and bottom of the mesa to inject or extract electrons from the dot across the double tunneling barrier resulting in a current flowing vertically, perpendicular to the 2DEG plane. Unlike in the PQDs, the tunnel barriers determined by the conduction band offset between the heterojunction materials are high (>100 meV) and thin (~ 10 nm), but are not electrically tunable, which makes them rather insensitive to external electric perturbations. While vertical confinement is relatively strong (e.g. ~ 10 – 20 nm), the VQD lateral size is similar to PQD as the diameter of the mesa (e.g. 100 – 200 nm). Fig. 1. (bottom) shows a scanning electron micrograph (SEM) of a typical mesa after gate deposition (Kouwenhoven et al., 2001).

Fig. 1 (Upper left) Schematic representation of a PQD structure with layered materials with the black areas denoting the confining metallic gates on the top surface. The 2DEG and the dot electrons show in pink, whereas the orange and dark red layered are the AlGaAs and undoped GaAs layers, respectively. (Upper right) Schematic of a VQD with the different constitutive materials; the vertical black areas on the sides are the controlling gates while the dot is represented by the light blue area sandwiched between the dark blue barriers (after Kouwenhoven et al., 2001). Self-assembled quantum dots

Self-assembled (SA) QDs are tiny self-crystallized islands arising from the epitaxial growth of a small band gap/large lattice constant semiconductor e.g. InAs on a larger band gap/shorter lattice constant substrate e.g. GaAs by the so-called Stransky-Krastanov technique. During growth of the first few layers of the small gap InAs semiconductor, the strain induced by the lattice mismatch between the two materials results into randomly distributed pyramidal nanostructures on the large band gap GaAs material. When recovered by another (or the same) large band gap, these islands form lens or disk-like shaped SAQD's, often of intermediate chemical compositions. Carrier confinement in SAQDs is much stronger ($\sim 10\text{--}20\text{ nm}$) in all directions than in PQDs or VQDs as a consequence of the band offsets between the strained materials, and consequently affects both the conduction and valences bands. Fig. 2A shows a 3D scanning tunneling microscope (STM) of a pyramidal InAs SAD grown on GaAs substrate with four clear facets along crystal directions indicated by their Miller indices (Marquez et al., 2001).

Silicon nanocrystals

Silicon nanocrystals (Si-nc) are nanoscale silicon (Si) crystals or Silicon-Germanium (Si-Ge) alloys embedded in a dielectric such as SiO_2 . These Si-nc's with a diameter ranging between 5 and 10 nm are usually produced through self-assembling process techniques involving low-pressure chemical deposition and oxidation. Hence, their size is not limited by lithographic resolution, but due to inherent variations in growth conditions during self-assembly, fluctuations in nc size, shape and coverage density are not

Fig. 2 (A) Three-dimensional STM image of an uncovered InAs QD grown on GaAs along the (001) direction. (B) TEM image of a Si-nc seeded in a SiO_2 dielectric grown on a silicon substrate (dark). The SiO_2 space between the Si-nc and the Si substrate forms a tunnel barrier 3 nm thick. un-common. In addition, high resolution transmission electron microscopy and X-ray analysis of Si-nc in Si/SiO₂ superlattices have revealed inhomogeneous strain ranging from 0.1% to 3.25% depending on the nc size and the process annealing temperature. The QDs are characterized by strong three-dimensional (3D) confinement of charge carriers that have provided the conditions to investigate single-electron charging effects and quantum phenomena at room temperature in Si materials with potential applications multi-bit floating gate memory. Fig. 2B shows a transmission electron micrograph (TEM) cross-section view of a Si-nc embedded in a SiO₂ and separated by 3 nm from a Si substrate (Tiwari et al., 1996).

Colloidal quantum dots

Colloidal quantum dots (CQD's) are semiconductor nanocrystals, generally III-V or II-VI compounds such as InAs, InP or PbS, PbSe or CdTe synthesized from solutions by traditional chemical or plasma processes. As their shape is controllable, but mostly spherical with diameters varying between 2 and 10 nm, their band gap is tunable which is used to select their wavelength of luminescence by recombination of the photoexcited carriers between conduction and valence bands (Kagan et al., 2016).

Key issues

Coulomb blockade and single electronics

The *Coulomb Blockade Effect* (CBE) manifests with ultra-small capacitances, when the addition of single electronic charge on a metallic island requires a discrete amount of energy to overcome the electrostatic repulsion caused by the other charges on the island. The "charging energy" is given by

$$E_C = \frac{e^2}{C} \quad (1)$$

where e is the electronic charge and C is the capacitance of the metallic island (Fig. 3 top.). The CBE was already observed with thin metallic films as early as the 1950s, and was fully explained by the so-called "orthodox theory" of Kulik and Shekhter, and Averin and Likharev in the mid 1980s (Likharev, 1999). In more recent experimental set-ups, electrons confined in a QD form an island isolated from a reservoir of charges by tunnel barriers that feed the QD with external electrons. In this configuration, the injection process is controlled by an electric gate capacitively coupled to the electronic island; electrons can then access the dot when the gate potential is large enough to overcome the repulsion of electrons in the dot. There are two conditions for the CBE to occur:

- The tunnel barriers to access the QD should be opaque enough to prevent the electrons from leaking back and forth between the dot and the reservoir, which can be expressed mathematically by the relation $R \gg \frac{h}{e^2} \sim 4 k\Omega$, where R is the barrier resistance and the right-hand side is called the *quantum resistance*. Another way to understand this condition is to ensure that the time spent by the electron in the QD i.e. the dwell time τ , is much larger than the charging time $\Delta\tau \geq \hbar/\delta E$ where δE is the level broadening of QD electrons resulting from the interaction with the reservoir.
- The charging energy should be much larger than the thermal energy i.e. $E_C \gg k_B T$, so that the effect wouldn't be smeared out by the noise and thermal fluctuations of the system. Fig. 3 (bottom (A)) displays a typical Coulomb staircase with the conductance peaks corresponding to the electron flow from the reservoir during the transition from N to $N + 1$ electrons in the QD, as depicted in Fig. 3 (bottom (B)) (Meirav and Foxman, 1996).

Single electronics

The ability to observe and control the CBE in QDs gave rise to the concept of "single electronics," where electronic function for applications in logic or memory are achieved by manipulating single electron charge in transistors. Among those, the single-electron transistor (SET) is a CBE-based three terminal device, where the number of electrons inside the dot and their one by one transfer from a *source* reservoir to a *drain* reservoir occurs through two tunnel junctions in series controlled by a *gate*. The SET principle of operation is similar to MOS field-effect transistor, where the active region is usually a PQD schematically depicted in Fig. 4A (Elzerman et al., 2003). Fig. 4B displays the SET channel conductance defined as $g_d = \partial I_{DS}/\partial V_{DS}$, and plotted as a function V_G , V_{DS} to exhibit the well-known two-dimensional (2D) diamond diagram illustrating the CB regime at $V_{DS} = 0$. For small V_{DS} ($\sim 150 \mu V$) in normal operation the continuous sweeping of the gate voltage generates a succession of CBE and single-electron tunneling events in the SET, such that the drain-source current exhibits so-called *Coulomb oscillations* (CO) with a gate voltage interval between two successive tunneling event (Fig. 3) (bottom (B)) given by

$$\Delta V_G = \eta^{-1} \left\{ \frac{e}{C_\Sigma} + \frac{1}{e} (\xi(N+1) - \xi(N)) \right\} \quad (2)$$

with $\eta = C_G/C_\Sigma$, $C_\Sigma = C_G + C_D + C_S$, where C_G , C_S and C_D are the gate, source and drain capacitances, respectively. Here $\xi(N) = \sum_{i=1}^N \epsilon_i(N) - \sum_{i=1}^{N-1} \epsilon_i(N-1)$ where $\epsilon_i(N)$ is the many-body energy level for the i^{th} configuration of N electrons confined under the SET gate. From Eq. (2) one defines the *quantum capacitance* of the dot as $C_Q(N) = \frac{e^2}{(\xi(N+1) - \xi(N))}$; the *addition energy* $E_a = e\eta V_G$, which is the amount of energy required to add an electron in the dot is then expressed as $E_a = e^2 \left(\frac{1}{C_\Sigma} + \frac{1}{C_Q(N)} \right)$.

Fig. 3 (Top) Basic concept of single electron charging on a conducting island. (Left) An external force F is needed to bring an electron on the neutral island carrying m electrons. (Right) The addition of a single electron now carries an electron charge that induced a repulsive electric field E to any additional electrons. (Bottom) (A) Schematic of a Coulomb staircase displaying the integer multiple of the electron charge on the dot as a function the QD gate voltage V_G . If C is the QD capacitance, the stair steps arise at equidistant ΔV_G . (B) Schematic plot of the QD conductance exhibiting peaks each time a electron access the dot. Memory applications

Another example of technological application of single electronics are Si or SiGe-nc's embedded as floating gate in the dielectric of a MOSFET structure for the realization of nonvolatile memories (Fig. 5) (Tiwari et al., 1996). Here, charge carrier injection (Fig. 5B) occurs from the transistor channel through a SiO_2 tunnel barrier between the transistor channel and Si-nc's distributed in the oxide, which induces a threshold voltage shift in the transistor (Fig. 5C). Reversing the gate voltage erases the information (Fig. 5D). Besides from the interest in the subtle quantum mechanics displayed by electron and hole charge carriers in the strong confinement of Si-nc's, these nanostructures have demonstrated several attractive features such as good data retention during charge storage, write/erase endurance characteristics, and short write time compared to conventional floating gate flash memories.

Artificial atoms and molecules

In the *classical limit*, achieved when the QD size is much larger than the electron de Broglie wavelength, λ_{dB} , the individual level spacing $\Delta\epsilon \ll E_C$, so that the second term in Eq. (2) is negligible compared to the classical charging energy e^2/C_Σ , which makes COs periodic in V_G . On the opposite, when the QD size shrinks and becomes comparable to λ_{dB} , the quantum capacitance C_Q adds a quantum mechanical contribution to the *addition energy*, so COs cease to be periodic with $\Delta V_G \approx \xi(N+1) - \xi(N)$ in the limit of small QDs. In this case, the *addition energy* E_a reflects the electronic structure of the three-dimensional confined states in the dot that can be describe with the quantum mechanical many-body Hamiltonian (Matagne and Leburton, 2004)

$$\hat{H}_{QD} = \sum_{i=1}^N \left[\frac{p_i^2}{2m^*} + V(\mathbf{r}_i) \right] + \sum_{i \neq j}^N \frac{e^2}{\epsilon |\mathbf{r}_i - \mathbf{r}_j|} \quad (3)$$

Here p_i and $V(\mathbf{r}_i)$ are the momentum and QD confining potential energy of the i^{th} electron, respectively. Eq. (3) resembles the Hamiltonian of atoms, except for differences in the potential shape and strength defined by the QD design, the particle effective

American Scientific Publishers.

mass m^* , and dielectric constant ϵ of the material. Because of those resemblances, QDs are called *artificial atoms*, exhibiting similar properties as natural atoms. Among the most salient ones is the existence of *atomic shells* governed by *Hund's rules* in highly symmetric e.g. 2D cylindrical PQDs and VQDs or 3D spherical CQDs. These atomic features emerge as *magic numbers* in the addition energy spectra of the dots when a shell is completely filled with electrons. Fig. 6 illustrates these *magic numbers* at 2, 6, 12, ... electrons filling successively the s-, p-, d-, ... quantum states in a 2D cylindrical QD with a harmonic (r^2 -dependent) confining potential. Here, the Coulomb stair case exhibits large steps for the 2nd and 6th electrons, whereas the shortest step for the 3rd electron is the manifestation of *Hund's rule*, for which the exchange energy between 2 parallel spins (3rd and 4th electrons) on different p-orbitals gives the more stable configuration (Matagne and Leburton, 2004).

Magnetic field effects

The presence of a magnetic field B parallel to the symmetry axis of the *artificial atoms* provides additional insight into electronic properties of the QD. Given the weakness of the electron binding energies (of the order of meV) combined with low electron effective mass m^* in materials like GaAs, relatively moderate magnetic fields of the order of 1 Tesla are sufficient to perturb atomic-like orbitals, while the weakness of the g-factor (-0.44 in GaAs) results in a tiny Zeeman splitting. In the absence of electron-electron interaction, the atom-like spectrum of 2D cylindrical harmonic potential with proper frequency ω_0 results in the well-known Fock-Darwin states (Maksym and Chakraborty, 1990)

$$E_{n,l} = (2n + |l| + 1)\hbar\left(\omega_0^2 + \frac{\omega_c^2}{4}\right)^{\frac{1}{2}} - l\hbar\omega_0/2 \quad (4)$$

where n ($= 0, 1, 2, \dots$) and l ($= 0, \pm 1, \pm 2, \dots$) are the radial and the angular momentum quantum numbers, respectively, and $\omega_c = eB/m^*$ is the cyclotron frequency. Fig. 7.a displays a typical Fock-Darwin spectrum as a function of B for $\hbar\omega_0 = 3\text{meV}$ (Kouwenhoven et al., 2001). It is seen that the $B = 0\text{ T}$ orbital degeneracy is lifted by positive and negative l energies with increasing B . The red-dashed line indicates the transition of the electron occupying the highest energy state to different orbital energy with increasing magnetic field.

Artificial molecules

Arrays of QDs coupled through tunnel junctions exhibit electronic properties similar to molecules, where electron states of individual dots couple to form covalent states that are delocalized over the entire arrays. These *bonding states* are lower in energy than the individual state by an amount equivalent to the binding energy of a molecule. In this context, a double QD is comparable to a *diatomic molecule*, for which the number of electrons can be varied by applying independent external voltages to the individual dots, while the quantum mechanical coupling among electrons can be tuned by varying the tunnel junction between the QD's. In the case of PQD's, vibrational motion of the *artificial molecules* can be mimicked by applying a RF voltage to the tunnel barrier. Fig. 8A shows the SEM view of a GaAs planar double QD systems with the different gates for carrier confinement and tunnel coupling (Elzerman et al., 2003), while Fig. 8B displays the 2D potential landscape of the planar double dot obtained by self-consistent simulation. Fig. 8C depicts a schematic of the lower atomic and molecular orbitals in the case of weak coupling (2D artificial atoms) and strong coupling (artificial molecules) between the dots (Matagne and Leburton, 2004).

Entanglement and quantum gates

Semiconductor coupled QD's are promising candidates for the realization of *universal quantum logic gates*, such as a controlled-NOT gate as the building block of a solid-state *quantum computer*. In such devices, the spins of two electrons S_1 and S_2 , each trapped in the

Fig. 7 Single-particle energies versus magnetic field B known as the Fock-Darwin spectrum for a particle in a parabolic potential with $\hbar\omega_0 = 3\text{ meV}$. Each orbital is two-fold spin degenerate. The red-dotted line highlights the evolution of the 7th and 8th electrons as a function of B . After Kouwenhoven LP, Austing DG, and Tarucha S (2001) Few-electron quantum dots. *Reports on Progress in Physics* 64(6): 701.

individual dots of the artificial *diatomic molecules* define individual quantum bits (*qubits*) of information. Their *entanglement* is the result of the *exchange interaction* J , equivalent to the energy splitting between the lowest singlet and triplet two-electron states, modulated by the voltage applied to the tunnel junction between the two dots. This energy difference directly determines the period of Rabi oscillations, which is the so-called $\sqrt{\text{SWAP}}$ operation time required for the exchange of information between the two qubits in a QD gate. The SWAP operator U_{sw} is such as $U_{sw} |ij\rangle = |ji\rangle$, if $|ij\rangle$ labels the basis states of the two spins in the S_z basis with $i, j = 0, 1$ (Loss and DiVincenzo, 1998). Fig. 9 illustrates the principle of the spin SWAP operation through a tunnel barrier between the two QDs controlled by an external gate voltage, whereas individual spin rotations will be performed by local electron spin resonance (ESR).

Optical emission from SAD's and CD's

Because of their tiny sizes and random distribution on substrate, SAD's and CQD's pose technical interconnection challenges to individual electrical access. Moreover, unlike PQD's and VQD's, for which carrier confinement is achieved in a single band (i.e. conduction band electrons), the strong structural confinement in SAD's and CQD's involves both the conduction and valence bands. For this reason, they are optically accessible for the investigation of inter-band transitions as well as of strongly *confined excitons* by Coulomb interaction between the atomic-like electron and hole states as a function of their size, shape and strain due to lattice mismatched between the host material and the dots (Bimberg et al., 1999). The absence of continuum and the existence of well-defined electronic states makes them perfect candidates for applications in optoelectronics such as QD lasers and QD photodetectors with well-defined wavelength

$$\lambda_{ij} = \frac{hc}{E_G + E_{c_i} + E_{v_j} - E_{xc_{ij}}} \quad (5)$$

where h is the Planck constant, c is the speed of light, E_G is the material bandgap, $E_{c_i}(E_{v_j})$ is the $i^{\text{th}}(j^{\text{th}})$ atom-like orbital energy in the QD conduction (valence) band that can be tuned by varying the dot size, and $E_{xc_{ij}}$ is the exciton binding energy for the i, j transition. Fig. 10A shows a schematic view of lens-shape InAs/GaAs SAD structure with a contour plot of the electron ground state inside the dots (Sheng and Leburton, 2002, 2003), while Fig. 10B displays the photoluminescence spectra of a truncated pyramidal SAD exhibiting three peaks corresponding to the electron-hole transitions indicated in the panel below, and broadened by the SAD size fluctuations. Except for the first peak caused by the strong inter-band matrix element between the electron and hole ground states, the two higher peaks result from combinations of electron-holes transitions among which the most salient are represented in Fig. 10C. SAD's can also produce *single-photon* sources in which the *photon polarization* is the *qubit* of *optical quantum gates* for applications in quantum information science. However, uniformity and repeatability issues become major challenges due to atomic-size control of such tiny objects made of only few hundred atoms, for which monolayer variation causes large fluctuations in the quantum spectra. In this context, unexpected inversion of the electron-hole dipole alignment for which the heavy mass

Fig. 8 (A) SEM of the top gates of a GaAs double PQD (white disks) integrated into a quantum circuit. The light gray areas show the different gates i.e. L&R gates control the left and right lateral confinement, T&M gates control the interdot electrostatic barrier, PL&PR are left and right plunger gates that control the electron number in each dot, and QPC-L and QPC-R are quantum point contacts that read the charge variation in each dot. The curved (straight) arrows show the QD (QPC) current charging (sensing) paths. (B) Corresponding electrostatic potential landscape simulated self-consistently by DFT device modeling. (C) Schematic representation of the six lower orbitals in an empty double PQD in the weak (left) and strong (right) inter dot coupling. In the former, the s -, p_x - and p_z -like orbitals are decoupled and degenerate within each dot. In the latter, the interdot interaction lifts the degeneracy of the p -states to form bonding and anti-bonding p_z -states, while the p_x -states are shifted up. The shaded area of the orbitals denotes the positive portion of the wavefunction. positive hole sits in the apex, while the lighter negative electron spreads at the base of the pyramidal or lens-shaped SAD may occur as a combination of strain and atomic inter-diffusion between SAD and substrate materials. Fig. 11 illustrates the effect of Ga-In atomic inter-diffusion that pushes the electron and hole ground states toward the apex of the pyramidal SAD, with a stronger effect on the hole state that develops wings along the ridges of the pyramid in an attempt to fit best in the space of the SAD (Sheng and Leburton, 2001).

Modeling and simulation

Given the 3D non-symmetrical geometry of QD's combined with their structural confinement, as in SAD's for instance, theoretical models assuming cylindrical parabolic confinement may have limited validity. For this purpose, 3D self-consistent computational approaches, such as density functional theory (DFT), Hartree-Fock, or exact diagonalization techniques in the case of PQD's or VQD's offer more comprehensive physical insight (Leburton, 2021). For SAD's, CQD's or Si-nc's, modeling based on tight binding

Conclusion

Often called “zero-dimensional” systems because of the absence of particle degree of freedom in 3D confinement, QD’s offer a rich variety of exciting phenomena by providing the structural conditions for manipulating *single quantum objects*, such as *single electrons*, *single spins* and *single photons* at the nanoscale. Besides from solid-state physics fundamentals at play at these scales, these effects bear promises for technological exploitation in single electronics for memory applications, high efficiency lasers, quantum information processing and quantum computing with the practical realization of photon-based and spin-based quantum gates. Recently, the emergence of 2D materials like graphene and transition metal dichalcogenides is providing new ground for the study of plane or 2D QD’s.

Abstract

A vertical stacking of quantum-dot layers at relatively high temperatures and low indium composition allows them to align laterally in uniformly sized and shaped dot chains. The quantum dots in a particular layer feel the ones underneath if the spacer layer between them is reduced to a certain extent. This kind of ordering is anisotropic due to the nature of the GaAs (001) substrate. While lithography techniques can achieve isotropic ordering, our motivation in this chapter is to show such ordering by controlling the growth parameters on GaAs without any processing. Changing different growth conditions, like substrate temperature, indium composition, background flux, and spacer layer thickness, in a systematic way allows for optimization of the growth parameters. Multilayers of InGaAs quantum dots have been grown and showed an excellent 2D ordering of quantum dots in chain-like structures. Finally, we demonstrate that with multi-stacked quantum-dot layers, the resulting GaAs surface can be used as a template to produce order in, for example, quantum rings grown on that surface.

Introduction

From the revolution that computing had in the 1980-ies through the diffusion of personal computers to the massive use of portable devices since the beginning of the 21st century, the search for new technologies that enhance the capacity of computing systems is increasingly necessary, facing new demands such as the development of artificial intelligence, for example. The capabilities of current computer systems are reaching their limits, and considerable potential for quantum computing to solve vastly complex problems is attracting ever greater attention and worldwide efforts to reach a new Epoch in modern civilization. In this sense, semiconductor materials, precursors of the first computational systems based on Si technology, can play again a fundamental role in developing quantum structures that can easily be incorporated into device manufacturing technologies today.

The new era of semiconductors should come with low-dimensional heterostructures (structures consisting of more than one semiconductor material with different energy band gaps) - candidates in developing quantum systems for processes and technologies that demand non-classical properties of matter. The motivations that stimulate research in this field are related to using these

materials to study fundamental properties and to employ new devices. However, despite considerable efforts in this field, many low-dimensional systems and their properties are still somewhat ambiguous and unsettled. The current research aims to fabricate and characterize new and unexplored low dimensional systems as, for example, III-V compound semiconductors (GaAs, InAs, InGaAs, AlGaAs). Many electrical and optical applications of semiconductors can be improved by using heterostructures to assemble devices. A whole family of structures exists within heterostructures at nanoscale dimensions that allow for confinement of electrons in one, two, or three dimensions. When the carrier motion in a solid is limited within the size of the order of the exciton Bohr radius in the bulk material, one will observe the effects of size quantization. In the case of quantum structures, the electrons are confined, and the energy levels are finite as distinct from a classical continuum. With the reduction of the size of bulk material (3D) to a thin slab (2D), the confinement can be continued until the motion of the electron is restricted in all three directions (quasi-0D), producing a point-like structure, or a quantum dot (QD), where the quantum properties can be manipulated leading to novel devices.

With decreasing the crystal size, all materials properties, such as mobility and effective masses of charge carriers, refractive index, oscillator strength of radiative transitions, transport properties, optical properties, and density of electronic states, change compared to the bulk material. The density of states changes from a smooth parabola in three dimensions to a staircase in a two-dimensional system and further to a δ -function in the zero-dimensional system. Manipulating a semiconductor material's physical properties presents a new chapter in fundamental physics. Moreover, many applications of nanostructures for novel devices have been predicted, such as single-electron transistors, quantum-dot lasers, and single-photon emitters, that can be used in technologies based on the quantum properties of matter, ranging from information technology and quantum computing to environmental protection. Although semiconductor quantum structures, such as quantum dots, have many potential advantages, the applications have been limited by the challenge of their growth process.

This chapter will discuss the procedures based on Molecular Beam Epitaxy to grow highly homogeneous and ordered self-assembled arrays of III-V semiconductor QDs. Vertically stacking QDs layers at relatively high temperatures and low indium composition allows them to align laterally in uniformly sized and shaped dot chains. This is because the dots in a specific layer feel the ones underneath if the spacer layer between them is reduced to a certain extent. This kind of ordering is anisotropic due to the nature of the GaAs (001) substrate. While lithography techniques can provide isotropic ordering, the motivation is to achieve such ordering by controlling the growth parameters on GaAs without processing. This is done by choosing different growth conditions, like substrate temperature, indium composition, background flux, the composition of the material, and spacer layer thickness, in a systematic way to optimize the growth parameters. Highly ordered semiconductor nanostructures like QDs have great potential for photonic devices.

Growth of self-organized semiconductor nanostructures

The fabrication of quantum-confined nanostructures by self-assembly using Molecular Beam Epitaxy has been intensively investigated for III-V semiconductors, particularly for the InGaAs/GaAs heterostructures. Due to the nontrivial geometry, the possibility of controlling the energy levels, oscillator strength, polarizability, and magnetic properties makes self-assembled quantum dots good candidates for developing new devices. The Stranski-Krastanov growth method produces self-organized, defect-free QDs, where the nanostructure growth is driven by strain and strain relaxation. Stacking is usually used to improve the size homogeneity, quantum efficiency, and unique distribution of self-assembled nanostructures.

Molecular beam epitaxy

Molecular Beam Epitaxy (MBE) was developed in the late 1970-ies and has played a fundamental role in developing heterostructure electronics and optics. MBE can create high-quality layers with sharp interfaces and suitable thickness, composition, and doping control. In the growth procedure, the wafer is placed into an ultrahigh-vacuum (UHV) environment (typically with a base pressure of $\sim 10^{-10}$ Torr) containing an array of shuttered ovens with various materials. When these cells are heated to a specific temperature, evaporation from the liquid or solid source material produces a molecular beam that can spread across the chamber and impinge on the wafer because of the large mean free path in the UHV environment. By changing the evaporation temperature of the source material, the beam flux can be controlled. The low growth rate of 1 $\mu\text{m}/\text{h}$ (~ 1 monolayer/s) guarantees the surface migration of the impinging species on the growing surface. The adsorbing atoms migrate across the surface and eventually incorporate with the substrate. Simple mechanical shutters placed in front of each cell are used to interrupt the beam fluxes, i. e., to start and stop the deposition. The MBE became a valuable tool in developing electronic and optical devices because of its high degree of control over material deposition. The UHV environment of MBE allows surface analysis tools, such as Reflection High-Energy Electron Diffraction (RHEED), to probe the surface properties and the growth mechanisms. Fig. 1 shows a schematic layout of a typical MBE growth chamber.

In epitaxial growth, a clean surface is necessary since contaminants from the atmosphere or other sources can easily reach a clean GaAs wafer and cause crystal defects or degrade the optical and electrical characteristics of the epitaxial layer.

Fig. 1 Schematic layout of the MBE growth chamber.

Molecular beam epitaxy growth modes

Depending on the system's energy balance and the lattice mismatch, there are three primary growth modes: Frank-Van der Merwe, Volmer-Weber, and Stranski-Krastanov (see Fig. 2).

The interface and surface energy relationship determines the growth mode in lattice-matched systems. If the surface energy of the epilayer is γ_e , the substrate surface energy is γ_s , the energy of the interface is γ_{se} , and $\gamma_e + \gamma_{se} < \gamma_s$, then the deposited material wets the substrate surface (Bimberg et al., 1998; Shchukin and Bimberg, 1999). In this case, the growth proceeds in the Frank-van der Merwe mode. If the energy of the interface between the two materials is high, $\gamma_e + \gamma_{se} > \gamma_s$, then the growth process will develop in the Volmer-Weber mode, directly coalescing into islands to reduce the interface area by increasing the surface area. For a strained epilayer with small interface energy, the initial growth may occur layer by layer, but a thicker layer has considerable strain energy and can lower its energy by forming isolated islands in which strain is relaxed. In this case, the Stranski-Krastanov (S-K) growth mode occurs (Bimberg et al., 1998).

The thermodynamic driving force for the S-K growth mode is strain and strain relaxation. In the S-K mode (where the materials are lattice-mismatched), the growth proceeds in three stages: first, a 2D deposition, then a 2D to 3D transition, and finally, the formation of the defect-free islands (Fig. 3). In the beginning, the growth will be in a layer-by-layer mode, with the epitaxial layers starting to accommodate their lattice structure to the substrate lattice constant, forming a wetting layer. The 2D growth phase will proceed until a critical thickness. At that thickness, the strain increases, and the excess energy stored in the 2D layer reaches the energy of the 2D-3D transition barrier. In other words, the strain becomes significant for the 2D growth to continue, and any further deposition of material will force the growth to proceed in the form of 3D islands to relieve the strain (Bimberg et al., 1998; Shchukin and Bimberg, 1999).

For example, in the case of InAs growth on GaAs, the first monolayer of InAs grows to form a strained 2D layer, while 3D QDs form when the thickness of the InAs layer exceeds 1.6 monolayers (ML).

Fig. 2 Diagrams of the three possible growth modes. (A) Frank-van der Merwe, (B) Volmer-Weber, and (C) Stranski-Krastanov.

Fig. 3 Stranski-Krastanov growth mode: first material deposited onto the substrate resulting in the strained wetting layer. After a critical thickness of the 2D layer, strain is relieved by forming a 3D island.

It is well-known that a rise in the growth temperature leads to a decrease in the QD density and a corresponding increase in the QD size (Raab et al., 2002). The increased QD size and reduced QD density as a function of temperature are due to the thermally activated increase of the adatom surface diffusion length at higher substrate temperatures, which results in increased separation of the QD nucleation sites as the growth temperature increases. For a fixed indium composition and layer thickness, the size and shape of these 3D islands vary by changing the growth temperature. The growth temperature directly governs the surface diffusion length, and as a result, a higher growth temperature yields elongated QDs (Ma et al., 2001). The reason is the anisotropy of the GaAs surface due to the (2×4) reconstruction and a high temperature (Kley et al., 1997). The increased QD size decreases the confinement energy in the QD, raising the growth temperature.

Self-assembled quantum rings

The formation of self-assembled quantum rings can be affected by many parameters, such as diffusion, strain, and surface and interface energies. All of them can be controlled by a proper choice of growth conditions. Diffusion can be influenced by changing the growth temperature and using cracked As_2 , which is more reactive than As_4 and reduces the mobility of the group III elements (Granados and García, 2005; Lorke et al., 2001; Lei and Lorke, 2014). Thus, elongated islands can transform into ring-like nanostructures. A possible scenario for the ring formation is depicted in Fig. 4.

At the growth temperature of 520°C , In atoms are very mobile on the surface, whereas the Ga atoms can diffuse little during the growth interruption (Lorke et al., 2001; Bressler-Hill et al., 1994; Llorens et al., 2018; Sanguinetti et al., 2014). As illustrated in panels (E) and (F) in Fig. 4, when atoms diffuse away from the QD, they stay fixed and do not go very far. Only then the relatively

Fig. 5 ($1\ \mu\text{m} \times 1\ \mu\text{m}$) Atomic Force Microscopy (AFM) images of (A) uncapped InAs QDs and (B) QDs after 4 nm GaAs capping layer under As_2 flux and 40s annealing. (C) 3D image reconstruction from 2D AFM showing a single quantum ring.

sharp outer edge of the rings can be obtained. This might be explained by the (InGa)As alloy formation (Granados and Garcia, 2003; Lorke et al., 2001). The model is based on kinetic considerations, namely differences in the surface diffusion rates of the indium and gallium atoms. Namely, the mobile indium atoms diffuse from the QD outwards, which allows them to avoid the original QD location (Lorke et al., 2001). The indium atoms diffuse into the surrounding GaAs crystal, forming an immobile ring-shaped InGaAs island (Lorke et al., 2001).

As shown in Fig. 4C, the relaxed InAs lattice constant at the top of the QD makes it a hostile site for the attachment of Ga atoms. Thus, the GaAs capping layer surrounds the dot like a blanket, see Fig. 4D (Lorke et al., 2001; Kegel et al., 2000; Mazur et al., 2007). Fig. 5 shows the AFM image of the formation of InGaAs QRs on a GaAs surface, as described in Fig. 4.

Controlling ordering on an array of quantum dots

The growth of the structure containing multilayers of InGaAs QDs separated by GaAs spacer layers will be referred from now to the vertical stacking of dots. The vertical stacking of QDs is important for most device applications because it allows one to increase the filling factor of QDs in a given sample and, therefore, to increase the quantum efficiency of the device. Different effects and morphologies arise depending on the thickness of the GaAs spacer layer between the vertically stacked InGaAs QDs layers and other growth factors. The strain from the InGaAs QDs layer transfers through the GaAs spacer and creates a strain field pattern on the spacer surface, which modifies the chemical potential of surface ad-atoms (Xie et al., 2000; Tersoff et al., 1996). The minimum chemical potential on the surface corresponds to the maximum tensile strain achieved directly above the buried islands. Therefore, ad-atoms are attracted to these points as nucleation centers and QDs align vertically according to the buried islands as more layers of QDs are stacked. The strain field created by the small islands is overwhelmed by the strain field from the neighboring big islands, leading to the annihilation of small islands in the next layer. This sequence is then repeated for each successive layer, and the island spacing and size become progressively more uniform.

The vertical alignment of QDs results in size and shape uniformity throughout the layer, reducing inhomogeneous broadening in optical output (Xie et al., 2000). So far, this vertical stacking cannot provide good control over the distribution of dots (i.e., lateral ordering). Although QDs with a high indium composition can achieve better uniformity than ones with a low indium composition due to the smaller size of QDs resulting from a lower coverage, they are not subject to lateral ordering. The vertical stacking of InGaAs QDs also affects their optical properties due to the interaction of the electronic wavefunctions from different QD layers if the spacer is not thick enough. If a very thin barrier (the GaAs spacer) barely covers the first QD layer or does not cover it entirely, the QDs in the stacked layers will be strongly coupled with each other. Such an electronic coupling directly affects the optical properties of the QDs. Stacking many layers (to increase the device efficiency) becomes impossible due to the high strain accompanied by further deposition. The increased strain is relieved by the generation of defects.

In the case of a spacer thickness that is not too small and enough for QDs to feel the strain modulation, the QDs do not undergo a strong electronic coupling between them. However, a tunneling of electrons might happen. The vertical correlation in the strain transfer is still effective and leads to the vertical alignment of QDs. For relatively thick (more than 40 nm) barriers, QD layers form independently of the underlying layers' strain effect. In such structures, a random formation of QDs would be a limiting factor for device application.

Lateral ordering of InGaAs quantum dots

The vertical stacking of QDs can, under special growth conditions, result in the lateral ordering of QDs on the surface. By growing InGaAs QDs with low indium composition at a relatively high substrate temperature (540 °C) and a suitable spacer thickness (15–20 nm), the lateral ordering of InGaAs can be achieved (Mazur et al., 2003). In that work, 2 nm $\text{In}_{0.36}\text{Ga}_{0.64}\text{As}$ QDs separated by 16 nm GaAs spacers are deposited. The images of surface morphology and cross-section view of such a structure are shown in Fig. 6, revealing the QD-chain features along the [0-11] direction. The vertical correlation is due to the vertical field of strain between the stacked QDs, as discussed before, while the lateral ordering is related to the enhanced ad-atom migration length and relieving the strain field along the [0-11] direction at a high growth temperature (Mazur et al., 2003). It is also noticed in Fig. 6B that the size and shape stability is achieved after 6 to 7 layers of QDs. QDs get bigger due to stacking as the density thins down, resulting in the lateral ordering.

Layer evolution in laterally ordered InGaAs QDs was studied (Wang et al., 2004a,b) by depositing 2, 7, and 12 layers of 9 MLs $\text{In}_{0.5}\text{Ga}_{0.5}\text{As}$ spaced by 60 MLs of GaAs. The QDs start to form at 4 MLs of InGaAs deposition in the first layer, while it took 3.4 MLs to form QDs in the following layer. The strain field induced by the buried islands directs the material in the second layer to local minima of lattice mismatch; hence, it takes less time to form QDs. The QDs start to line up laterally after seven layers.

It is observed that lateral ordering is accompanied by the continuous reduction in the island density and the increase in the average island size in the subsequent layers. It has also been revealed (Wang et al., 2004a,b) that the QDs are already lined up along the [0-11] direction in the initial stage of 3.7 MLs of InGaAs deposition, which indicates that it is the nucleation rather than the ripening that is responsible for the formation of QD chains. Based on these results, favored nucleation of QDs along the chain direction is the most likely scenario for forming QD chains. This explanation requires that the strain field transferred through stacked layers of QDs has to be anisotropic. The total energy calculations of the pure migration of Ga atoms on the GaAs(001)-(2 × 4) reconstructed surface have been performed (Kley et al., 1997) and predicted an activation barrier of 1.2 eV along the As dimer rows (i.e., along the [0-11] direction) and 1.5 eV across them (i.e., along the [011] direction). This means that adatoms diffuse easier on the surface along the [0-11] direction than along the [011] direction, resulting in the elongated shape of dots in a single layer.

Furthermore, under the normal growth conditions of QDs (using As_2 flux as a background), the GaAs surface resembles a (2 × 4) surface reconstruction (Salmi et al., 1999). It is clear that the arsenic dimer rows run along the [0-11] direction and create anisotropy in the GaAs surface energy. Adatom diffusion during the formation of QDs relaxes the strain along [0-11] direction, creating an anisotropic strain field that is transferred through stacked layers. This leads to the formation of QD chains along the [0-11] direction. It is fair to say that a combination of anisotropic strain field and enhanced adatoms diffusion are the primary factors controlling the formation of vertically stacked QD chains. It is expected that the growth temperature would affect the formation of QD chains since it controls the diffusion of adatoms, as discussed above and as will be explained below in this chapter.

Fig. 6 (A) Dark-field cross-section TEM image of multilayered InGaAs QDs and (B) AFM image of the sample surface.

Ordering evolution from single layer to vertically stacked QDs layers

The $3\ \mu\text{m} \times 3\ \mu\text{m}$ AFM images in Figs. 7 and 8 represent the morphology of an $\text{In}_{0.4}\text{Ga}_{0.6}\text{As}$ QDs surface layer for single and multilayered (16 MLs) $\text{In}_{0.4}\text{Ga}_{0.6}\text{As}$ QDs, respectively. The left-hand-side images of each figure show QDs, which were grown under As_4 , while the right-hand-side images ones grown under As_2 . Low indium composition responds to the anisotropy of the GaAs (001) surface by forming 1D chains along the $[0-11]$ direction. The surface anisotropy can be tuned by an intentional miscut to introduce different types of steps with different densities along the $[0-11]$ direction. A miscut toward $[0-11]$ (or $(111)\text{B}$ surface) creates B-type steps, which run along the $[011]$ direction. The B-type surface steps along $[011]$, which are perpendicular to the $[0-11]$ direction for GaAs (100), are characteristic of the $(n11)\text{B}$ surfaces. For the used surfaces, $(311)\text{B}$ and $(511)\text{B}$, the step size is $6\ \text{\AA}$ and $10\ \text{\AA}$, respectively (Wang et al., 2004a, Wang et al., 2004b; Lee et al., 2002). Introducing surface steps with known densities in a

The top right-hand-side insets of the images represent the FFT of the surfaces that shows the correlation between the QD's nearest neighbors.

Fig. 8 ($3\ \mu\text{m} \times 3\ \mu\text{m}$) AFM images of multilayered (16 layers) $\text{In}_{0.4}\text{Ga}_{0.6}\text{As}$ QDs grown under As_4 (left-hand-side images) and As_2 (right-hand-side images). The top right-hand-side insets of the images represent the FFT of the surfaces that shows the correlation between the QD's nearest neighbors.

direction perpendicular to the chains obtained in the (100) surface creates a new surface diffusion direction for the migration of adatoms. When the density of steps along the $[0-11]$ direction in the $(n11)\text{B}$ surfaces is comparable to the natural corrugation of the (100) 2×4 surface reconstruction, the 1D ordering behavior changes to a 2D ordering as observed in the (311)B and (511)B surfaces. The right-hand-side top inset in the AFM images represents the modulus of the Fast Fourier Transform (FFT) of the AFM region. The FFT shows the correlation between the QD's neighbors. For one layer QDs (Fig. 7), the ordering changes from a chain-like (1D) to a 2D diffuse square-like for the (311)B and (511)B surfaces. The ordering obtained for the multilayered structures is enhanced due to the strain transfer from the InGaAs QDs layer through the GaAs spacer that creates a strain field pattern on the spacer surface, which leads to the modulation of the chemical potential of surface adatoms. The minimum chemical potential on the surface corresponds to the maximum tensile strain achieved directly above the buried islands. Therefore, adatoms are attracted

to these points as nucleation centers, and QDs align vertically according to the buried islands as we stack more QDs layers. This cycle is repeated for each layer, and the island spacing and size become more uniform. It is important that the ordering behavior is due to surface properties combined with the growth conditions, and the stacking improves it. The usage of As_2 instead of As_4 decreases the diffusion of Ga along the $[0-11]$ direction for (100) surface. The isotropic diffusion mechanism under As_2 can be explained by surface energy. The total energy calculations of the pure migration of Ga atoms on the GaAs (001)- (2×4) reconstructed surface have been performed, and they predict an activation barrier of 1.2 eV along the As dimer rows (i.e., along the $[1-10]$ direction) and 1.5 eV across them (i.e., along the $[011]$ direction). However, theoretical calculations have shown that the excess arsenic lowers the energy barrier for hopping in the $[011]$ direction to a value closer to the barrier height in the $[0-11]$ direction. In this case, the Ga atom is transformed from a one-dimensional random walker to a two-dimensional random walker. Our results reflect that As_2 has a similar effect as a very high As_4 flux but without the need for lowering the temperature and hindering diffusion. Experimentally, it has been shown that the As_2 species affect diffusion similarly to high As_4 pressure (Ripalda et al., 2003). This explanation has also been adapted as the cause of isotropic diffusion necessary for the formation of quantum rings (Kley et al., 1997).

A reduction of diffusion of the group III atoms is due to both the effect of As_2 and the surface steps for high-index surfaces. The decrease of the Ga adatoms diffusion causes a reduction in the lateral intermixing of InGaAs along the $[0-11]$, $[-233]$, and $[-255]$ directions, and this increases the separation between the QDs along the above-mentioned directions. The AFM images also reveal an increase in the QDs volume (height and diameter) when using As_2 . For one layer QDs, the average densities drop by 10% with the usage of As_2 from the value of 1.5×10^{10} QDs/cm² obtained for As_4 QDs. Compared to QDs obtained using As_4 , the QDs produced with the help of As_2 are 10% bigger in height (with an average of 8 nm) and more rounded; consequently, their average size distribution has a 10% narrower width.

The effect of As_2 is more pronounced in the multilayered QD structures. As the GaAs template changes due to strain field modulation, the diffusion length increases for Ga (see above), particularly for the (100) GaAs surfaces. The multilayered QD density produced under As_4 flux is slightly lower than the average density obtained for a single layer of QDs with the help of As_4 because the obtained QDs are slightly bigger due to staking. The stacking using As_2 leads to a 20% decrease in the QDs density from 1.3×10^{10} cm⁻² for QDs obtained with As_4 . This decrease in intensity causes an increase of 15% in height (with an average of 10 nm) for the multilayered QDs obtained under As_2 flux. Also, the average size distribution has a 15% narrower width.

The decrease in the size distribution with As_2 flux was also observed in PL measurements. Fig. 9 shows 10 K PL spectra of single and multilayer $\text{In}_{0.4}\text{Ga}_{0.6}\text{As}$ QDs grown on the (100) GaAs surfaces under (a) As_4 flux and (b) As_2 flux. The PL spectra for multilayered QDs by changing the growth environment from As_4 to As_2 reveal two significant features. First, the PL peak position is blue-shifted, and second, the FWHM is narrowed to 58 meV for the sample obtained with As_4 flux to 31 meV for the sample produced under As_2 flux. Despite the increase of the QD height from the sample (a) to the sample (b), the PL peak is blue-shifted

Fig. 9 PL spectra of single and multilayer (16 layers) $\text{In}_{0.4}\text{Ga}_{0.6}\text{As}$ QDs grown under (A) As_4 flux and (B) As_2 flux.

from (a) to (b). This is because QDs in the sample (a) behave more like quantum wires due to the lateral overlap between QDs along the chain direction. On the other hand, QDs in the sample (b) are well separated and behave like QDs with greater confinement resulting in a net blue shift. For a single QDs layer, the FWHM narrowing is due to the squeezing of the QD size distribution. All these results are consistent with the effect of the As_2 background.

Role of the indium composition

The indium composition is directly proportional to the strain relieved along the $[0-11]$ direction to form anisotropic ordering. For this reason, the present section is aimed at understanding of the role of strain on lateral ordering by changing the indium composition. It is well known that increased compressive strain on the QD will hinder the migration of adatoms on the GaAs surface. This is understood because indium atoms do not diffuse as fast as Ga atoms on the GaAs surface. Also, a higher indium composition increases the strain in the InGaAs layer and makes QD formation faster. For those reasons, QDs with a higher indium composition have less response to surface anisotropy and less relief to the strain in the $[0-11]$ direction than QDs with a lower indium composition. It is interesting to examine the effect of changing the indium composition on the vertically stacked QDs to seek the possibility of changing the anisotropic ordering. Before the growth of multi-stacked layers to observe the lateral ordering, four single-layer InGaAs QD samples were grown with different indium compositions (In%), as shown in Fig. 10. This step was needed to understand the effect of the indium composition on the shape and size of QDs in the first layer as it affects the successive ones. These samples were grown at 540°C with different amounts of the InGaAs coverage, which was set to be around 25% above the critical thickness depending on the indium composition. For $\text{In}\% = 0.3, 0.4, 0.5$, and 1 (i.e., InAs), the InGaAs coverage was 15, 8, 6, and 2 MLs, respectively. These samples were grown under a standard MBE growth environment (i.e., As_4 molecules as a background flux).

Table 1 summarizes the QDs' dimensions of the four samples obtained by AFM line scans. The parameters $\text{In}\%$, h , dx , dy , T_C , and T_A refer to the indium composition, average QD height, average QD diameter along the $[011]$ direction, critical QD diameter along the $[0-11]$ direction, and the actual deposition, respectively. These parameters are the same in all experiments described below unless otherwise mentioned.

Fig. 10 AFM top views of one-layer InGaAs QDs with indium composition of (A) 0.3, (B) 0.4, (C) 0.5, and (D) 1.

Table 1 A summary of the average QD parameters for samples shown in Fig. 10.

Sample	In%	$h(\text{nm})$	$dy(\text{nm})$	$dx(\text{nm})$	$T_C(\text{MLs})$	$T_A(\text{MLs})$
(a)	0.3	6.0 ± 0.7	50 ± 7	70 ± 18	12.0	15.0
(b)	0.4	7.0 ± 0.5	43 ± 6	45 ± 6	6.4	8.0
(c)	0.5	6.5 ± 0.6	38 ± 8	38 ± 8	4.8	4.8
(d)	1	5.5 ± 0.5	25 ± 5	25 ± 5	1.6	1.6

It was observed that a lower indium composition led to bigger QDs on the surface and resulted in elongated dots along the $[0-11]$ direction due to the anisotropy of the adatom migration length in response to the (2×4) surface reconstruction. On the other hand, the adatom migration length and lateral intermixing after the QD formation was very low while depositing InAs QDs. In the present case, the critical thickness of InAs was 1.6 MLs, so only 0.3 MLs were deposited after that. The data in Table 1 show that QDs with a higher indium composition had smaller diameters and a more isotropic shape. To investigate the effect of stacking layers, four multilayers InGaAs QDs structures were grown at 540°C with the same sequence of the indium composition and the amount of InGaAs deposition as the single-layer samples shown in Fig. 10.

The AFM images of the multilayer samples are shown in Fig. 11, and their corresponding dimensions are summarized in Table 2. The new parameters used in Table 2 are the average dot diameter (d) and the average spacing between the QDs' centers along the chain (y) and across chains (x), and other parameters are similar to those defined above. Comparing samples (a) through (d) reveals the effect of the indium composition on the lateral ordering of stacked QDs. In contrast, InGaAs samples with a lower indium composition responded to the anisotropy of the GaAs (001) surface by forming quantum wires along the $[0-11]$ direction, QDs are formed at a higher indium composition due to the higher strain dominating over adatom diffusion. Although increasing the indium composition made the QDs better defined and non-overlapping along the chain, the higher indium composition also resulted in a lower density, short-chain lengths, and, eventually, no chains at all for the case of InAs. The conclusion was that increasing the indium composition reduced the diffusion and elongation of QDs along the $[0-11]$ direction, which, in turn, affected the lateral ordering with stacked layers of QDs. The vertically stacked QDs with an indium composition higher than 0.4 were less pronounced along the chains and separated from each other as the indium composition increased. However, at the same time, that increased the strain transfer while stacking QD layers, leading to a bigger area of influence of a QD to the next layer. This led to a reduced QD density when stacked since the deposition amount was smaller and increased the chain-to-chain separation. QD chains were shorter

and further apart with the increased indium composition, and eventually, no ordering for the InAs QDs was observed. The next investigation was to find a way to reduce the diffusion of adatoms along the $[0-11]$ direction but without increasing the strain.

Low indium composition under As_2

The drawback of the sample with $\text{In}\% = 0.3$ was the presence of coalescence between QDs. The QD coalescence is due to an increased coverage (Thibado, 1999). The other three samples were grown under As_2 flux, with 30% indium composition, but with a reduced InGaAs deposition from 15 MLs to 13.5 and 12 MLs (Fig. 12). These three samples were compared to the one grown with 15 MLs deposition and shown in Fig. 11. It was observed that reducing the amount of InGaAs to 13 MLs, as in Fig. 12B, impressively resulted in a 2D lateral ordering of QDs with hexagonal geometry. The visual image was supported by the FFT of the AFM image shown in the inset of Fig. 12B. A magnification of this ordering is presented as the image Fig. 12D.

Fig. 12C showed that reducing the amount of the InGaAs deposition to 12 MLs captured the initial formation stage of QDs over the GaAs surface. However, there were two interesting observations obtained from Table 3. First, the QDs' smaller size, and second, the QDs' alignment in chains. In the areas where QDs were not yet formed, the wetting layer was wire-like corrugated along the $[0-11]$ direction as favorable areas for QDs to nucleate. This was similar to how QDs with higher indium compositions were ordered, as seen in earlier experiments. This observation supported the earlier conclusions that smaller QDs are subject to anisotropic ordering due to low coverage. It is instructive to examine the QD ordering shown in Fig. 12D. Each QD is surrounded by the six nearest neighbors resembling a honeycomb pattern. An interesting scenario could be as follows: It is known that each QD transfers a vertical strain to the QD layer above. When two QDs are very close to each other, the profile of the transferred strain pattern overlaps with each other and only one nucleation site in the layer above from the two sites below provides a vertical ordering mechanism and reducing the QD density. As the density reduces, each QD resides at nearly the center of a circle of radius R of influence, where there are no other QDs. As a result, assuming each QD is at the center of a circle of influence, six QD circles can

neatly fit around one QD because there is no longer any favored direction of diffusion when using As_2 . The final trial was to balance the indium composition and coverage. It was thought that growing QDs with $\text{In}\% = 0.35$, for example, would result in smaller QDs than those in the case of $\text{In}\% = 0.3$ because of a reduced deposition time. This was expected to make the size uniformity better than in the case of $\text{In}\% = 0.3$. At the same time, the strain would be less than the case with $\text{In}\% = 0.4$, so QDs would have more chance to be 2D ordered. Growing QDs with $\text{In}\% = 0.35$ was then expected to make them inherit the desirable characteristics of size uniformity and 2D ordering. Multilayer $\text{In}_{0.35}\text{Ga}_{0.65}\text{As}$ QDs samples were grown under As_2 flux by depositing 11 MLs of InGaAs. The AFM scan of such a sample is displayed in Fig. 13. The size and shape uniformity was better for the sample with $\text{In}\% = 0.35$ than in the case of $\text{In}\% = 0.3$. At the same time, the hexagonal 2D ordering was still preserved, as shown in the FFT (inset to Fig. 13).

The growth of QDs under the As_2 environment reduced the anisotropic diffusion of Ga adatoms and made QDs well separated, and at low indium composition, dramatically reduced the strain factor and made QDs bigger in size, so that separations between QDs along and across the chain became comparable. This allowed the formation of isotropic 2D laterally ordered QDs, and, consequently, 3D ordered arrays of QDs due to the vertical correlation. At the same time, the achieved ordering reflected the uniformity of QDs, which, in turn, improved their optical properties.

Ordered self-assembled quantum ring arrays

The growth of quantum rings (QRs) was a remarkable development in the self-assembly of semiconductor nanostructures. QRs are formed with the help of the Stranski-Krastanov growth method. In this approach, a partial capping of large InAs QDs with a thin layer of GaAs results in the formation of QRs. During the annealing step at the growth temperature, a topology change occurs: the original QDs acquire a hole in their center and take on a ring-like shape, as described in Section “Growth of self-organized semiconductor nanostructures.”

The growth of patterned arrays of QRs can be obtained on the GaAs(100), (311)B, and (511)B surfaces on multilayered templates of InGaAs/GaAs QDs, as described in Section “Controlling ordering on an array of quantum dots.” It was observed (Wu et al., 2012; Wu and Wang, 2014), that it was possible to produce chains of QRs on the GaAs(100) surface (see Fig. 14). Individually, the QRs on the (100) surfaces were seen to have an elliptical geometry with a minimum inner radius of ~ 25 nm. The average radii of QRs on all three samples of ordered QRs are presented in Table 4.

These averages were calculated by taking the first derivative of the AFM height data. The places where this first derivative changes its sign corresponds to the rings' center and edges. The standard deviations are similar from sample to sample, but the average radii are larger on the high-index surfaces (311)B and (511)B. More material is typically necessary when growing dots on high-index surfaces than on the (100) surface. This is because the effective lattice constant of a high-index surface is generally larger than that of the (100) surface. Therefore, the strain due to the lattice mismatch is smaller per unit volume of material deposited than on the (100) surface. This means that QDs form later in the growth on a high-index surface than on the (100) surface, similar to the QDs shown in Figs. 7 and 8 in Section “Controlling ordering on an array of quantum dots.” So, the QDs are larger, leading to larger QRs whenever partial capping is performed.

Fig. 14 AFM Topography of QR chains on the InGaAs/GaAs(100) multilayered structure.

Table 4 Average radii of ordered QRs on the GaAs(100), (311)B, and (511)B surfaces.

Surface Miller Index	Average radius (nm)	Standard Deviation (nm)	Figure number
(100)	26.3	8.2	14
(311)B	37.6	10.7	15
(511)B	35.2	7.5	16

The averages were calculated by analyzing the first derivative of the AFM height data.

It was supposed that the elliptical shape was because the QRs evolved out of slightly elongated QDs in the [0-11] direction. In addition, the adatom diffusion may be more favorable in the [0-11] direction. The maximum height of the QRs on (100) was about 1.4 nm, while the width (defined as the outer radius minus the inner radius), was about 25 nm. In general, it was observed that the QR chains did not persist for more than about 2 μm on QD chains. One can expect to achieve QR chains that persist for over 2 μm under the optimum growth conditions.

The AFM topography of the samples grown on the (311)B and (511)B surfaces, shown in Figs. 15 and 16, indicates very clearly defined QRs with inner diameters on the order of ~ 40 nm, widths of ~ 30 nm, and a maximum height of ~ 1.5 nm relative to the sample surface in between the QRs.

Moreover, these QR arrays possessed not only 1D ordering on the surface of the substrate but also 2D ordering. The QRs on both the exposed (311)B and (511)B surfaces appeared to be arranged in a 2D array, as expected.

Fig. 17 shows the 2D FFTs of the three samples, which is evidence that the QRs grown on them display long-range ordering.

The FFT for the (100) surface shows ordering along the horizontal axis, which indicates that they may be called QR chains. However, the FFT indicates ordering along more than one direction on the (311)B and (511)B surfaces. For example, it looks like the pattern on the (311)B surface has two axes of symmetry and that the one on the (511)B surface may have as many as four axes of symmetry. The FFT for the (511)B surface appears to have the hexagonal symmetry (as shown in Fig. 11B), and that for the (311)B surface appears to have rhombic symmetry. For this reason, it is possible to consider these arrays of QRs on the (511)B and (311)B surfaces as 2D lattices of QRs with hexagonal and orthorhombic symmetry, respectively.

Fig. 18 Distribution of QR radii on the (100), (311)B, and (511)B surfaces.

Data showing the distribution of QR sizes are shown in Fig. 18. The average size corresponds to the values in Table 4 in all cases except the data for the (511)B surface.

In addition, one notices that the distribution data for the (311)B surface indicate a bimodal size distribution of the QRs. Interestingly, this implies the occurrence of two groups of InAs QDs on the GaAs surface prior to the partial capping that causes the above-described transition to QRs. The data for the (100) surface seem to point on this bimodality, with a small group clustered around 35 nm in the distribution.

Conclusion

In general, this chapter's main focus was exposing the underlying physics in the fabrication and characterization of self-assembled III-V compound semiconductor nanostructures. We also propose a combination of properties to control the ordering of QDs and QRs on a GaAs surface using natural surface anisotropic for (100), surface steps on high index GaAs substrates, and the Arsenic background. Ordered QDs with low indium composition on GaAs (001), (311)B, and (511)B were obtained for one and multilayered structures. We found that the ordering is due to surface properties combined with the growth conditions. The stacking only enhances the initial order provided by the surface properties and the growth conditions. We observed that using As_2 molecules as opposed to As_4 molecules as a background environment, we can modify the surface kinetics and combine this property with the diffusion of adatoms over the surface. We found that the change of the Arsenic background environment from As_4 to As_2 increases the separation of the QDs from each other without eliminating the lateral ordering and decreases their size distribution. Narrow QDs size distributions resulting from As_2 are useful for applications such as lasers and detectors and will improve their advantages.

Abstract

Rolling-up prestrained nanomembranes combining the merits of top-down and bottom-up approaches, enables the fabrication of multilayered tubular microstructures. The great flexibilities in the tailoring of 3D morphologies and material compositions accelerate the discovery of numerous novel optical properties. For all-dielectric rolled-up microcavities, the whispering gallery mode resonances, axial optical confinements, and optical mode interactions in both weak and strong coupling regimes are discussed. These properties render the structure a great platform for studying optical spin-orbit coupling and non-Hermitian photonics. For microtubes consisting of both dielectrics and noble metals as anisotropic metamaterials, unique optical properties are discussed including optoplasmonic mode hybridization and dispersion engineering.

Key points

- Microtube structure formed by self-assembly of strained nanomembrane
- Optical resonances in rolled-up tubular structures
- Resonant mode response to weak external perturbations
- Mode splitting and non-Hermitian photonics
- Optical spin-orbit coupling in rolled-up microcavities
- Optoplasmonic hybridization
- Rolled-up metamaterials

Introduction

The “rolled-up nanotech” was developed at the beginning of the new millennium, firstly on semiconductor thin film fabricated using molecular beam epitaxy (MBE) (Schmidt and Eberl, 2001; Prinz et al., 2000). Nowadays, it is considered to be one of the most promising “origami” (a kind of talented paper folding art) technology, and usually termed “rolling origami.” Rolled-up 3D micro/nanostructures can be constructed by engineering strain gradients in the stack of 2D nanomembranes. In early works, the internal strain in nanomembranes was incorporated by exploiting the crystal lattice mismatch between two different materials such as InGaAs and GaAs. The lattice mismatch creates a differentially strained bilayer causing an up or downwards rolling.

For a typical rolling-up process, the sacrificial layer is firstly prepared on top of a substrate. Then, strained nanomembranes are deposited onto the sacrificial layer in a step-by-step manner. By etching the underneath sacrificial layer, these strained nanomembranes are released from the substrate and tend to force themselves into free-standing 3D cylinder structures to stabilize their elastic energy (see Fig. 1a). For such a self-rolling process, the nanomembrane can be bilayer or multilayer. Besides, it has been shown that a single layer of materials, e.g., silicon, can also be rolled due to the strain gradient. Over the development of more than 20 years, numerous efforts have been continuously invested in extending the compatibility of the rolling process with highly diverse nanomembrane materials, including metals, oxides, semiconductors, 2D materials, etc. (Xu et al., 2019).

The most common rolled-up 3D microstructures are tubes and helices. For a simple bilayer case assuming the equal Young's modules and Poisson ratios, the rolled-up tube diameter D can be estimated as follow:

Fig. 1 (a) Top-view SEM image of a rolled-up nanomembrane with a circular nanomembrane pattern. (b) SEM image in a cross-sectional view after a focused ion beam (FIB) cut. The zoomed-in view suggests the sub-wavelength tube wall thickness. Modified with permission from (2013) *Advanced Materials* 25: 2357; Copyright © 2013 WILEY-VCH Verlag GmbH & Co. KGaA.

Fig. 2 Sketch of rolled-up nanomembrane and nanomembrane strip in the cross-sectional view to show the azimuthal WGM resonances, including a spiral ring (left-up), a perfect ring after approximation (right-up), and a strip expanded from a curved waveguide (bottom).

$$D = \frac{1}{3\varepsilon(1+\mu)} \frac{(d_1 + d_2)^3}{d_1 d_2} \quad (1)$$

where ε is the in-plane biaxial strain between layers, μ is the Poisson ratio, d_1 and d_2 are the thickness of two membrane layers, respectively. Typically the demonstrated D is in the range of $\sim 1\text{--}100\ \mu\text{m}$. The wall thickness depends on the thickness of the deposited nanomembrane layer and the winding number $w = L_{\text{roll}}/\pi D$, where L_{roll} is the total rolling length along the rolling axis. As presented in Fig. 1b, a microtube with wall thickness down to $\sim 130\ \text{nm}$ can be realized.

Besides, the rolling-up process combines the advantage of both top-down (through patterning of the planar membrane geometry) and bottom-up (through strain-modulated self-assembly) strategies. The key morphology of the cylindrical structure, including the size, wall thickness, design along the axial direction, and asymmetric rolling condition can all be finely tailored. Therefore, the enabled great versatility opens up infinite potential in exploring novel optical properties and developing optical and optoelectronic applications.

Here, the following sections elaborate on the discovered optical properties of rolled-up micro/nanostructures made by different materials covering dielectrics, semiconductors, and metals. A tubular-shaped microcavity allows good light confinement through whispering gallery mode (WGM) resonance, and therefore is regarded as a powerful platform for unveiling rich physical insights, including light field manipulation in 3D space, cavity-enhanced light-matter interactions, external and internal mode couplings. Besides, the adjustable structural and material anisotropy in the rolling process results in intriguing properties such as optoplasmonic hybridization, spin-orbit coupling, and anisotropic metamaterials. All these introduced properties have been unleashing the huge potentials of miniaturized optical and optoelectronic devices, such as light sources, detectors, sensors, and waveguiding/routing elements for on-chip photonic integrated circuits (PICs), etc.

Optical resonances in rolled-up tubular structures

As one of the well-known optical resonances in microstructures, optical WGM is the exact counterpart of acoustic resonances discovered at the gallery surface of St Paul's Cathedral and systematically explained by Lord Rayleigh. In the optical regime, it describes the light trapping and propagating along the concave boundary of a dielectric structure due to total internal reflection (TIR). Optical WGM cavities in a circular or rounded shape can be roughly categorized into two types, namely solid-core ones (e.g., microspheres, microdisks, microtoroids, microbottles, and fibers) and hollow-core ones (e.g., microrings, microtubes, and

microbubbles). Supposing that the tubular nanomembrane is cut and expanded into a strip with a total length of L (i.e., the circumference), light propagation within a rolled-up cavity can be considered as a similar case in an optical planar waveguide (see Fig. 2). TIR of light occurs with the incident angle $\theta < \theta_c$. By curving the waveguide into a loop, WGM resonances can be built up by constructive interference of light traveling around the tube circumference. A longitudinal resonance condition is introduced as

$$Ln_{\text{avg}}k \sin \theta = 2m\pi \quad (2)$$

where m stands for the “azimuthal” mode order in a ring form, n_{avg} accounts for the refractive index of the multilayered nanomembrane. Usually, n_{avg} can be estimated by averaging the refractive index along the multilayer wall structure. The following formula is used

$$n_{\text{avg}} = \sqrt{\frac{\sum t_i n_i^2}{\sum t_i}} \quad (3)$$

where each subscript refers to an individual layer in the multilayered tube wall, and t_i is the thickness of the i^{th} layer on the tube wall (with the refractive index n_i), respectively.

WGM resonances can be understood by calculations of 2D Helmholtz equation for cylindrical ring model,

$$\left[\nabla_{r,\varphi}^2 + \left(n(r) \frac{\omega}{c} \right)^2 \right] \Phi(r, \varphi) = 0 \quad (4)$$

where $n(r)$ is the refractive index profile along the radial direction.

The analytic solution in cylindrical coordinate is

$$\Phi(r, \varphi) = \begin{cases} C_A J_m(n_c k r) & r < R_1 \\ C_B J_m(n_{\text{avg}} k r) + C_C Y_m(n_{\text{avg}} k r) & R_1 \leq r \leq R_2 \\ C_D H_m^{(2)}(n_0 k r) & r > R_2 \end{cases} e^{\pm i m \varphi} \quad (5)$$

where $J_m(\cdot)$, $Y_m(\cdot)$, and $H_m^{(2)}(\cdot)$ are Bessel and Henkel functions, $k = \omega/c$ is free space wave vector, and m is the azimuthal mode number. The unknowns in Eq. (5) are coefficients (C_A , C_B , C_C , C_D) and the wave vector k . One can match the boundary conditions of the field and its derivative at $r = R_1$ and $r = R_2$ and get rid of the coefficients (C_A , C_B , C_C , C_D) by using a matrix method.

Due to the difference in boundary conditions, polarization degeneracy of light is lifted. And usually transverse electric (TM, $E_z = 0$) modes and transverse magnetic (TE, $H_z = 0$) modes will be separately calculated with different values of k . For TE mode ($\mathbf{E} = E_z \mathbf{z}$), we can match the boundary conditions of the field and its derivative at $r = R_1$ and $r = R_2$ and get rid of the coefficients (C_A , C_B , C_C , C_D) by using a matrix method.

For TM mode, at $r = R_1$

$$C_A J_m(n_c k R_1) - C_B J_m(n_{\text{avg}} k R_1) - C_C Y_m(n_{\text{avg}} k R_1) = 0 \text{ and } C_A J'_m(n_c k R_1) - C_B J'_m(n_{\text{avg}} k R_1) - C_C Y'_m(n_{\text{avg}} k R_1) = 0 \quad (6)$$

At $r = R_2$

$$C_B J_m(n_{\text{avg}} k R_2) + C_C Y_m(n_{\text{avg}} k R_2) - C_D H_m^{(2)}(n_0 k R_2) = 0 \text{ and } C_B J'_m(n_{\text{avg}} k R_2) + C_C Y'_m(n_{\text{avg}} k R_2) - C_D H'_m^{(2)}(n_0 k R_2) = 0. \quad (7)$$

Here the derivative notation $' = d/dr$. We can write the functions into a matrix equation and use a standard eigenvalue solver to obtain k and associated resonant energies E_m . Once the resonant energy of the interesting mode is obtained, the spectrum, 1D and 2D field profiles can be easily generated, as illustrated in Fig. 3.

For optical resonances, it is common to adopt the quality factor Q to describe the energy storing ability

$$Q = 2\pi \frac{\text{Energy stored}}{\text{Energy dissipated per cycle}} = \frac{\omega}{\Delta\omega} = \frac{\lambda_r}{\Delta\lambda_r} \quad (8)$$

where λ_r , ω_r are the resonant wavelength and frequency, and $\Delta\lambda_r$, $\Delta\omega_r$ are the corresponding linewidths.

For theoretical studies as the ideal case, the Q -factor mainly limited by the radiative loss can be calculated from

$$Q = \frac{\text{Re}\{E_m\}}{2\text{Im}\{E_m\}}. \quad (9)$$

In practice, the absorption, Rayleigh scattering in bulk materials, and scattering due to surface roughness all have significant contributions to the loss. The total Q factor can be written as

$$\frac{1}{Q_{\text{total}}} = \frac{1}{Q_{\text{rad}}} + \frac{1}{Q_{\text{abs}}} + \frac{1}{Q_{\text{sca}}}. \quad (10)$$

For nanomembrane microcavities, the ultra-thin cavity wall (e.g., 100–200 nm) may lead to the only observation of TE mode due to the poor confinement (low- Q) for TM mode and strong radiative loss. To support both TE and TM modes, a sufficiently thick wall (e.g., 200–300 nm for modes at visible wavelengths) is required. To this end, one can either increase the winding number w , or perform post-fabrication deposition of dielectric materials (e.g., by atomic layer deposition).

It is worth noticing that the aforesaid discussion treats the rolled-up tube as a microring with perfect rotational symmetry. There is a double degeneracy for each of the azimuthal modes with a certain polarization state, namely the clockwise (CW) and

Fig. 3 (a) Schematic of a resonant spectrum covering five WGMs with different azimuthal mode number m . (b) Numerically calculated mode intensity profile at a cross-sectional view for mode with $m = 38$.

counterclockwise (CCW) modes, which can be lifted by introducing scatters and breaking the symmetry. Here, the rolling process intrinsically leads to a spiral ring with two rolling edges (i.e., one inner and one outer). Detailed discussions on mode splitting will be in section “Mode splitting and non-Hermitian photonics.”

Split axial modes in 3D microtube cavities

For direct rolling of a regular nanomembrane pattern (e.g., square shape), the WGMs confined in the microtube suffer from severe substrate leakage loss due to direct contact with the substrate. It is desired to tailor the 2D membrane geometry to seek a free-standing segment so that high efficiency of light confinement and high Q factors can be obtained. Alternatively, the 2D nanomembrane can be tailored into a U-shaped design, as presented in Fig. 4a. After rolling with a predefined distance, the middle part of the patterned nanomembrane is fully rolled up while the rest two side parts continue to roll a certain distance more, leading to a self-supporting microtubular “bridge” where the middle of the rolled-up structure is separated from the substrate.

In addition to the U-shape design, the peculiar property of rolled-up nanomembrane here is that it offers an additional degree of freedom along the axial direction (i.e., z -direction) for tailoring the 3D cavity shape and manipulating the optical resonance (Strelow et al., 2012). Here the winding number $w(z)$ at the middle segment can be freely designed, leading to tailored optical confinement along the axial direction and the single azimuthal mode split into multiple axial modes.

Taking into account the tailored tube structure and its resulted optical confinement along the axial direction, the eigenmodes of a 3D microtube microcavity can be theoretically analyzed by solving the Helmholtz equation (4). Considering the cylindrical coordinates (Fig. 4b), the wave equation is expressed as follow:

$$-\frac{1}{n^2(r, \varphi, z)} \nabla^2 \vec{E}(r, \varphi, z) = k^2 \vec{E}(r, \varphi, z) \quad (11)$$

where k is the wavevector and n is the averaged refractive index (taking account of multilayered nanomembrane).

As the dynamic of WGM occurs mainly in the r - ϕ plane, an adiabatic approximation is applied to separate the terms of electric fields between circular and axial propagations.

Here taking the TE mode as an example, the electric field can be written as:

$$E_z(r, \varphi, z) = \Phi(r, \varphi, z) \Psi(z) \quad (12)$$

where $\Phi(r, \varphi, z)$ is the circulating term and is the axial term.

By rewriting the scalar Helmholtz equation, one has,

$$-\frac{1}{n^2(r, \varphi, z)} \nabla_{r, \varphi}^2 \Phi(r, \varphi, z) = k_{\text{circ}}^2(z) \Phi(r, \varphi, z) \quad (13)$$

Where k_{circ} is the absolute value of wavevector circulating in the r - ϕ plane at a specific z . Eq. (13) can be decomposed into a scalar quasi-Schrodinger equation,

$$-\frac{1}{n^2} \frac{\partial^2}{\partial z^2} \Psi(z) + k_{\text{circ}}^2(z) \Psi(z) = k^2 \Psi(z). \quad (14)$$

Fig. 4 (a) SEM image of a rolled-up microtube based on a U-shaped pattern design. (b) Schematic showing a 3D tubular cavity and its corresponding light WGM resonant trajectory in a cylindrical coordinate. (c) Numerically calculated mode energies upon a parabolic-shaped optical quasi-potential (upper) and the 3D mode profile (lower) for axial modes with mode numbers $q = 0, 1$, and 2 . Panel (b): Modified with permission from (2019) *ACS Sensors* 4: 1476; Copyright © 2019 American Chemical Society.

The structured nanomembrane rolling length and the winding number along z -direction lead to a tailored distribution of $n(z)$ and $k_{\text{circ}}(z)$.

The Eq. (14) does not have a general solution. Notably, the equation form is highly analogous to a particle-wave in a one-dimensional potential. As an example, the middle part of a nanomembrane can be designed with a parabolic-shaped lobe (Fig. 4a). Such a parabolic quasipotential here leads to equidistant mode spacing. Fig. 4c shows the numerically and measured axial modes with almost equal mode spacing. The mechanism behind is highly similar to the bulgy structure in microbubbles for 3D optical resonances. The great flexibility of lobe design offers rich possibilities for manipulating axial modes, while the morphology of microbubbles is highly rigid and limited by the effect of surface tension.

Rolled-up microtubes as optically active and passive devices

Due to the good optical confinement, it is advantageous to incorporate a gain medium into the nanomembrane along with the rolling process so that microtubes can be easily turned into an efficient light source. Optically and electrically pumped microlasers have been demonstrated by structuring optically active quantum wells inside the multilayered nanomembrane. Other gain media, like defects in oxide, dye molecules, colloidal quantum dots, and perovskites, are all proved to be highly feasible in turning the cavity into an efficient single-mode laser or broadband light source. Fig. 5 shows the emission spectrum collected from a SiO/SiO₂ bilayer nanomembrane-based tube with a diameter of $\sim 10 \mu\text{m}$ with a lobe design. Through optical pumping, the light emission due to natural defects in amorphous nanomembrane layers leads to coupling of photoluminescence (PL) light into multiple cavity modes with both different azimuthal and axial mode numbers. By tailoring the axial confinement, the typical Q factor can be improved from $\sim 10^2$ – 10^3 to $\sim 10^4$, which is attributed to the mitigated scattering and leakage loss along the axial dimension. The remaining factor preventing further pushing a higher Q factor is the intrinsic scattering loss by the two rolling edges.

Rolled-up microcavities can also work as optically passive microcavities. Probing the optical resonances can be accomplished by evanescent coupling. Tapered nanofibers (Fig. 6) and on-chip integrated waveguides (Fig. 7) serve as two main approaches for coupling with the modes. Here the light was launched from the input laser source and no intrinsic emitters are needed. By sweeping the input wavelength, resonant modes can be discerned as transmission dips.

In recent years, integrating the rolled-up microtube onto planar waveguiding devices is a significant step forward in transferring the microtube into functional integrated devices, as presented in Fig. 7. In particular, the whole process can be compatible with standard CMOS-compatible fabrications in silicon-based PICs. It is envisaged that microtubes serve as out-of-plane integrated

Fig. 5 Measured PL spectrum of a rolled-up microtube with higher order axial modes supported by axial confinement.

Fig. 6 (a) Optical image of a microtube cavity coupled with a tapered nanofiber. (b) Transmission spectrum measured by tapered fiber coupling with a microtube cavity. Higher order axial modes are revealed due to 3D optical confinement in the microtube cavity.

Fig. 7 Optical image showing a microtube directly integrated on top of the waveguide as a monolithic integration technology.

passive microrings as filters, switchers, and routers, or active devices like waveguide-coupled light sources. The 3D resonances in 3D tubular cavities reveal one natural advantage of simultaneous coupling with multiple independent waveguides or devices, while its studies in multiplexed and even 3D integration are in the inception stage.

Mode responses with weak external perturbations

For resonances confined in microstructures, evanescent fields act as a bridge between the inner and outer environments, which provide a way to tune the trapped light and sense the external perturbations. As to built-up WGMs in rolled-up microtubes, any polarizable (bio)molecules or nano-sized particles around the surface will interact with the evanescent field, and cause a slight change in the optical path length (OPL) as the product of the effective refractive index n_{eff} and the distance L . Similar to other WGM-based sensors, the change of resonance wavelength can be expressed as follow:

$$\frac{\Delta\lambda_r}{\lambda_r} = \frac{\Delta n_{\text{eff}}}{n_{\text{eff}}} + \frac{\Delta L}{L}. \quad (15)$$

The relative resonance mode shift can be described according to perturbation theory. It is correlated with the ratio of the interaction energy divided by the total energy:

$$\frac{\Delta\lambda_r}{\lambda_r} = \frac{\alpha_{\text{ex}} |E(r_i)|^2}{2 \int \epsilon |E(r)|^2 dV}, \quad (16)$$

where α_{ex} is the polarizability of the external object, r_i is the binding site and $E(r_i)$ is the local electric field at the tube surface interacting with the analyte.

Over the development of more than one decade, rolled-up optical microcavities have been widely investigated with the demonstrated capabilities of refractometer sensing, cell/microparticle detection, surface sensing, molecule dynamic binding, humidity sensing, gas sensing, etc. (Wang et al., 2019a). For two widely-known scenarios, namely detection of bulk liquid samples and absorbed molecules at the surface, two different terms of spectral sensitivity are defined:

$$S_{\text{bulk}} = \frac{\Delta\lambda}{\Delta n}; S_{\text{surf}} = \frac{\Delta\lambda}{\Delta\sigma} \quad (17)$$

where Δn is the refractive index change of the liquid sample, and $\Delta\sigma$ is the surface density of molecules homogeneously bonded to the tube surface.

Owing to the ultrathin cavity walls ($\sim 100\text{--}300$ nm), strong evanescent fields at the tube surface facilitate the light-matter interactions and thus enable an ultra-sensitive detection process. For bulk liquid sensing, calibrated spectral sensitivity using a rolled-up microtube indicates a sensitivity S_{bulk} close to 1000 nm/RIU, which is roughly one order of magnitude higher than those in optical sensors with a planar design (e.g., microrings).

By virtue of the ultra-thin tube wall and intense evanescent field, rolled-up microtubes are particularly suitable for real-time detection of a surface molecular dynamic process. As an example, the dynamic evolution of nanoscale water layers on a tube surface of amorphous oxide can be probed by optical resonances (Yin et al., 2019). The interaction between absorbed molecules and the evanescent field leads to two remarkable effects (Fig. 8a). The first one is the resonant mode shift due to the increase/decrease of molecular layer thickness. The estimated molecular layer thickness in such a surface sensing process can be extracted by perturbation theory, as presented in Fig. 8b. By spectrally resolving the tiny wavelength shift, the detection limit can be lower than monolayer water molecules. The second one is the resonant mode linewidth change due to the altered molecular landscape on the surface and affected scattering. Consequently, one can find out the transition point between two morphologies, planar film, and pyramid-like nanoclusters during the growth and desorption processes.

Mode splitting and non-Hermitian photonics

In addition to optical mode response upon tiny perturbations discussed in the previous section, a strong external perturbation may lead to a much higher coupling strength and very different phenomena. One well-known example is a photonic molecule consisting of two or multiple closely-packed identical optical cavities, generating prominent mode hybridization. Another example is a chain of coupled resonators, so-called coupled-resonator optical waveguides (CROWs), in which a tight-binding model can be applied for understanding the mode splitting.

For coupling in a two-mode system (Fig. 9a), this can be analyzed using a 2×2 Hamiltonian matrix

$$H = \begin{pmatrix} E_1 & V \\ W & E_2 \end{pmatrix} \quad (18)$$

Fig. 8 (a) Schematic showing the resonance mode shift and mode broadening effects due to molecular binding. (b) Calculated mode shift as a function of molecular layer thickness using perturbation theory. Fig. 9 Schematic of coupling in two-mode systems, including (a) a two-element photonic molecule. (b) a microtube with an embedded microsphere at the hollow core. (c) a microtube placed on top of a planar microring. (d) a microtube with two concentric high-index layers and a low-index spacing layer.

where V and W are the cross-coupling strengths. For general cases of external coupling via the continuum, $W \neq V^*$, the matrix H is non-Hermitian (Cao and Wiersig, 2015). The eigenenergies can be expressed as

$$E_{\pm} = \frac{E_1 + E_2}{2} \pm r \quad (19)$$

and

$$r = \sqrt{\frac{(E_1 - E_2)^2}{4} + VW}. \quad (20)$$

Here a simple case of internal coupling ($V = W^*$) is discussed. For the original resonant modes at two cavities that are spatially separated from each other, energy transfer is inefficient, and the eigenenergies are almost unperturbed. While the real part of original mode energies become aligned for resonant coupling $\text{Re}(E_1) = \text{Re}(E_2)$, one can adjust between two coupling regimes. For weak coupling $|V| < V_c$ with $V_c = |\text{Im}(E_1) - \text{Im}(E_2)|/2$, spectral crossing can be observed in the real part of eigenenergies. For strong coupling $|V| > V_c$, there is anticrossing for the real part of eigenenergies. As a function of the real-valued wavelength detuning parameter $\Delta = |\text{Re}(E_1) - \text{Re}(E_2)|$, the real part of eigenenergies come close but then repel each other. Usually, the two eigenvectors of the hybridized modes are non-degenerate. The exceptional point (EP) as a transition point between two regimes where the two or multiple eigenvalues coalesce together with their associated eigenvectors, can be reached by fine adjusting the coupling condition.

Here due to the strong evanescent field exposed outside and inside the tube wall, by transferring other WGM microcavities, it is feasible to create composite photonic molecules, e.g., microtube-microsphere (Fig. 9b), microtube-microring (Fig. 9c), and multilayered-microtube-microtube systems (Fig. 9d), etc. The coupling strength can be manipulated by adjusting the mode field overlap between two cavities. The flexibility of selectively exciting specific axial modes leads to controllable coupling strength between strong and weak coupling regimes. The interaction of strong coupling can be corroborated by the characterized spectral anticrossing.

Apart from coupled microcavities, discrete rolled-up microtubes with a deformed cavity shape are recognized as a promising platform for studying non-Hermitian photonics. The gradual increase of the radius at the cross-sectional view gives a spiral ring shape. The boundary can be defined as.

$$r(\varphi) = R \left(1 - \frac{\varepsilon}{2\pi} \varphi \right) \quad (21)$$

Where φ is the azimuthal angle that is determined by the winding number $\varphi = 2\pi w$, and the deformation parameter ε is the thickness of a single nanomembrane layer. At the starting and ending rolling positions, two nano-sized rolling edges are generated, which act like local nanoscatterers with both out-coupling of internal fields and internal coupling between CW and CCW lightwave components. For out-coupling of internal fields, the symmetry breaking turns the originally isotropic emission into deterministic bi-directional emission at two rolling edges toward the far-field (Wang et al., 2019b). The adjustable orientation (i.e., azimuthal position) of two rolling edges located at different axial positions leads to free manipulation of emission angles for multiple resonance modes. The emission can be switched between bi-directional emission and uni-directional emission regimes, which is attributed to the beating effect of CW and CCW lightwave components. The intrinsic mechanism is the de-tuned mode chirality, namely the ratio of CW and CCW lightwave components of the emission mode.

Therefore, the natural symmetry breaking in rolled-up microtubes offers a fascinating platform for studying non-Hermitian photonics. For internal coupling of CW and CCW propagating modes in a rolled-up microtube (Fig. 10), the 2×2 Hamiltonian matrix can be written as:

$$H = \begin{pmatrix} E_0 & 0 \\ 0 & E_0 \end{pmatrix} + \begin{pmatrix} \Gamma & A \\ B & \Gamma \end{pmatrix} \quad (22)$$

where E_0 is the original equal eigenenergy, Γ is the original scattering rate, $A(B)$ is the backscattering from the CW (CCW) to the CCW (CW) propagating mode. The strength of backscattering can be efficiently tuned by the azimuthal position of two rolling edges. Hence, the hybridization can be switched between strong and weak coupling regimes.

Fig. 10 Schematics showing mode internal coupling between CW and CCW components in a microtube with a spiral ring-shaped cross-section. The interaction is dependent on the two rolling edges induced unbalanced backscattering (left), and can be readily tuned to EP with a clear mode chirality (right).

For EP as a transition point between two regimes, $A = 0$ or $B = 0$, both the eigenenergies and eigenvectors collapse to a single one. Hence, $\psi_{\pm} \propto \begin{pmatrix} 1 \\ 0 \end{pmatrix}$, indicates the clear chirality of the EP. Engineering of rolling edges in either rolling process or post-fabrication modification is exploited for transforming the system to the EP, which is highly promising for cavity light-field associated applications, including unidirectional emission and chiral sensing.

Optoplasmonic hybridization in metal/dielectric rolled-up structures

Surface plasmons originate from collective electron oscillations at the interface between a noble metal (e.g., Au, Ag, Cu) surface and a dielectric under optical excitation. Surface plasmon modes, including both propagating surface plasmon polaritons (SPPs) or localized surface plasmon resonances (LSPRs), feature deep subwavelength confinement (ultra-small mode volume) and highly intense near-field effects enhancement. Typically, the huge absorption loss of metals severely reduces the Q factors of plasmonic modes. The combination of a dielectric rolled-up microtube and decorated plasmonic nanostructures lead to optoplasmonic hybridization. By combining a dielectric rolled-up microtube and decorated plasmonic nanostructures, optoplasmonic hybridization leads to compensation of metal loss by cavity-field build-up (Chen et al., 2021).

As illustrated in Fig. 11a, a simple model of a microtube (wall thickness of T) coated by a uniform metal thin film (thickness of t) is investigated by numerical simulations. For conventional hollow-core microcapillary cavities ($T/R \gg 0.1$), the large T limits the mode overlapping and the hybridization effect is very weak. Due to the ultrathin cavity wall of microtube cavities ($T/R < 0.1$), the evanescent field largely facilitates the hybridization of metal nanostructures on the tube surface. The electric field of the TM-polarized mode (electric field direction perpendicular to the tube wall) is perpendicular to the metal-cavity interface, which matches the oscillation direction of the surface plasmons, resulting in the hybrid modes, stronger tunneling of lightwave out of the outer boundary suggests an intensified evanescent field (Fig. 11b and c). In contrast, TE mode results in a coupling mismatch between the cavity photons and the surface plasmons and hence suppressed lightwave tunneling at the top surface. In other words, the TE mode just experiences a “shielding” effect by the metal layer and hybridization is negligible (Fig. 11c). In practice, a straightforward and efficient mode hybridization scheme is to introduce a metal nanocap fabricated by physical vapor deposition on top of a rolled-up tube.

Another intriguing phenomenon is the hybridization between LSPRs generated from discrete metal nanostructures (e.g., particles, gaps) and WGMs in rolled-up microtubes. Due to the large mismatch of mode volumes, the coupling behavior is strongly dependent on the spatial overlapping condition. For LSPR-induced local hotspots overlapping with the antinodes of one WGM with a specific axial and azimuthal mode order, the hybridization effect is maximized. In practice, nanoparticles on the tube surface can be fabricated by localized annealing or transfer of chemically synthesized nanoparticles. A straightforward way of generating plasmonic nanogaps is to deposit a gold nanofilm onto the out rolling edge with a pre-defined orientation (Fig. 12). The rolling edge serves as a local step with the height equal to the thickness of a single nanomembrane layer ($\sim$ tens of nm), hence enabling LSPRs around this nanogap and selective coupling with WGMs.

Spin-orbit coupling in rolled-up cavities

For rolled-up microtubes based on the circular nanomembrane pattern, the two sides are lifted from the substrate but the light might still be strongly trapped at the middle segment due to the relatively higher n_{eff} . In order to avoid strong leakage, the design of asymmetric cone-like optical microcavity is exploited. Interestingly, for a circular-shaped 2D nanomembrane geometry, a varied

rolling axis during the rolling process leads to a cone-like optical microcavity. The radius of the microtube along the axial direction $R(z)$ is no longer uniform. The axial optical quasi-potential well is established around the larger-diameter-end part, so that optical resonances can be well confined at the lifted segment at the side instead of the middle segment. In particular, this symmetry breaking unleashes rich insights in photon spin-orbit coupling and generation of Berry phase (Ma et al., 2016).

Here the discussion starts with a common cylindrical ring-like microcavity, the light propagating trajectory is cyclic with a close path. The wave vector k experiences a trivial evolution when propagating along a closed loop. There is no possibility to generate the spin-orbit interactions, as optical angular momentum (OAM) along the tube axis is always orthogonal to the wave vector k (indicating the direction of the spin angular momentum (SAM)). In such a system, the optical polarization states are conserved at each resonance.

At the larger-diameter-end part of a cone-shaped tube, the variation in the number of windings leads to a resonant trajectory that slightly tilts out of the plane (Ma et al., 2016). Fermat's principle states that the trajectory light takes between two points is the trajectory that has the minimum OPL. In the larger diameter side of the tube, the variation of windings along the tube axis results in distinct thick and thin parts (with thickness T_1 and T_2 , respectively). The lengths of the spiral cross sections are obtained by integrating the middle radius ($R_{\text{int}} + T_i/2$, $i = 1, 2$) of the thick part (with length L_1) and thin part (with length L_2) of the spiral tube wall. They are

$$L_1 = \int_0^{\theta_1} \left(R_{\text{int}} + \frac{T_1}{2} \right) d\theta \quad (23)$$

$$L_2 = \int_{\theta_1}^{2\pi} \left(R_{\text{int}} + \frac{T_2}{2} \right) d\theta \quad (24)$$

where θ_1 is determined by the portion in the length of the thick part ($\theta_1 = 2\pi L_1/(L_1 + L_2)$). Hence, Eqs. (23) and (24) must be solved in a self-consistent way.

Here, the trajectory of light is assumed to be within a flat plane which has a tilt angle β with respect to the horizontal plane ($\beta = 0^\circ$). The OPL of the light trajectory can be calculated,

$$\text{OPL} = n_{\text{avg}}^1 L_1(\beta) + n_{\text{avg}}^2 L_2(\beta) \quad (25)$$

where n_{avg}^1 and n_{avg}^2 are the averaged refractive indices for the thick and thin part. The calculation result in Fig. 13 indicates the light should travel along a slightly inclined trajectory ($\beta \sim 2.5^\circ$) in accordance with Fermat's principle. The tilt angle at the minimum of OPL depends on the tube geometry (i.e., the inhomogeneity of the tube wall).

Therefore, in an inhomogeneous conical ring, a tilted non-planar light trajectory is expected. The electric field vector rotates around the tube axis due to the cone shape of the microtube, generating an effective OAM along the tube axis. The tilted trajectories break the orthogonality between SAM and OAM, and enable spin-orbit coupling (Fig. 14).

The polarization state for light circulating in a cavity is determined by three factors: (i) the ordinary interference path, (ii) the spin-orbit coupling of photons, and (iii) the medium anisotropy. For an initial polarization state in terms of the Jones vector $a = \begin{pmatrix} a_+ \\ a_- \end{pmatrix}$ comprising of right $a_+ = \begin{pmatrix} a_+ \\ 0 \end{pmatrix}$ and left $a_- = \begin{pmatrix} 0 \\ a_- \end{pmatrix}$ circularly polarized basis, the final (time-invariant) polarization state can be calculated as follow:

$$a = \begin{pmatrix} a_+ \\ a_- \end{pmatrix} = \frac{1}{\sqrt{2}} \exp \begin{pmatrix} -i\varphi & iC_A \\ iC_A & i\varphi \end{pmatrix} \begin{pmatrix} 1 \\ 1 \end{pmatrix} \quad (26)$$

where $\mp i\varphi$ denotes the acquired geometric phase, the non-diagonal element iC_A denotes the coupling and mutual conversion between two circular polarization components.

Here, the conversion of amplitudes between the two circular components leads to a change from a linear to an elliptical polarization, which is in contrast with the orthogonal mode pairs (TE and TM modes) in symmetric rolled-up microtubes and other WGM microcavities with rotational symmetry. Moreover, the geometric phase causes the orientation of the major axis of the polarization to tilt by an angle (equal to φ) with respect to the initial orientation.

Rolled-up metamaterials

For an anisotropic optical material, one of its components of the dielectric permittivity tensor has a different sign from the others. Two decades ago, researchers have investigated superlattices of different materials with thickness in the sub-wavelength scale for anisotropic materials that cannot be found naturally. Rolled-up nanotech serves as a unique and elegant route to generate alternating layers consisting of metal, dielectric, or semiconductors, and produce anisotropic metamaterials with tunable surface curvature.

Curved metamaterials can be readily obtained by rolling strained bilayer nanomembrane composing one layer of dielectric and one layer of metal, as illustrated in Fig. 11a. Based on the effective medium theory, the radial and tangential permittivity of the rolled-up hollow-core tubular structure can be written as:

$$\varepsilon_\theta = \frac{t_d \varepsilon_d + t_m \varepsilon_m}{t_d + t_m} \quad (27)$$

$$\varepsilon_r = \frac{\varepsilon_d \varepsilon_m (t_d + t_m)}{t_d \varepsilon_m + t_m \varepsilon_d} \quad (28)$$

where ε_d and ε_m are the permittivity of the dielectric and metal, respectively, and t_m and t_d are the ratios of thickness for metal and dielectric in a single nanomembrane bilayer ($t_m + t_d = 1$).

For TE polarization, the dispersion relation is

$$\frac{k_\theta^2}{\varepsilon_r} + \frac{k_r^2}{\varepsilon_\theta} = \frac{\omega^2}{c^2} = k^2. \quad (29)$$

For ε_θ and $\varepsilon_r > 0$, the dispersion curve is like an ellipse. While $\varepsilon_\theta < 0$ and $\varepsilon_r > 0$, it changes into a hyperbolic shape (see Fig. 15b).

The structure was implemented into the idea of creating a lens, i.e., hyperlens, which could image beyond the diffraction limit (Schwaiger et al., 2009). Due to the conservation of the angular momentum, subwavelength details can be magnified by a ratio $V = r_{\text{outer}}/r_{\text{inner}}$, where r_{outer} and r_{inner} are the outer and inner radius of the rolled-up tubular structure. Then the evanescent waves at the near-field can be converted to propagating waves in the far-field for imaging using classical optics. Considering the dielectric layer as an optically active layer (e.g., quantum wells), the same concept has also been applied to adjusting responses of emitters, such as enhancement of Purcell factor and emission directionality.

Besides, the 3D hollow-core structure with great flexibility in dispersion engineering renders it a good candidate for metamaterial fiber optics. The hyperbolic dispersion allows waveguiding of surface plasmon polariton as a propagating mode inside the superlattice structure (Smith et al., 2010).

Conclusion

In summary, we present an overview of rolled-up tubular architecture that is formed by strained nanomembranes. As a rapidly advancing nanotechnology with ~ 20 years of history, it stands out featuring various merits: (i) great flexibility in incorporating a plethora of materials covering dielectrics, semiconductors, and metals, (ii) feasibility of fine tailoring the scale, morphology and structural symmetry by novel 2D nanomembrane geometry design, (iii) good compatibility for on-chip standard mass-production technology on wafer levels for on-chip monolithic integration.

The unique optical properties of rolled-up nanomembrane structures have been discussed in multiple sections. The huge possibilities in microtubular structure bring fresh understanding into fundamentals like cavity QED, non-Hermitian photonics, anisotropic metamaterials, spin-orbit coupling, etc. (Fomin, 2021). Therefore, it is envisioned that the rolled-up nanomembrane-based devices and systems will bring about highly promising applications as light sources, detectors, sensors, and building blocks in on-chip photonic and optoelectronic systems.

Abstract

The relevant length scales for superconductivity are of the order of nanometers. By confining the superconducting condensate to such dimensions, many physical properties change substantially, and novel phenomena emerge, which are absent in the pristine material. We discuss various methods of creating artificial nanostructures by top-down approaches in metallic and copper-oxide superconductors and their applications. Such nanostructures can be used to control magnetic flux quanta in superconductors, anchoring them to engineered defects to avoid dissipation, guiding their motion, or building artificial flux-quanta arrangements. Nanopatterned superconductors are essential for creating model systems for basic research and enable building almost dissipationless and ultrafast electronic devices and highly sensitive sensors.

Key points

- The properties of a superconductor substantially change when the superconducting condensate is confined to the nanoscale.
- Methods of nanopatterning superconductors are reviewed.
- Focused helium ion beam irradiation provides a novel technique to fabricate nanostructures in copper-oxide superconductors.
- Vortex pinning landscapes, guided vortex motion, vortex ratchets, and superconducting diodes are discussed, and their application as elements of superconducting low-dissipation electronic circuits are outlined.
- The fabrication of Josephson junctions by focused ion beam irradiation and their properties are discussed.

Introduction

Superconductivity originates from the long-range coherence of bosonic quantum particles that condense into a lower energy state and is thus called a macroscopic quantum phenomenon. One might wonder what could be the advantage of confining the superconducting condensate to the nanoscale? The answer lies in two essential characteristic lengths that characterize superconductivity. The Ginzburg-Landau coherence length ξ determines the distance over which the density of superconducting carriers can change from its peak value to zero and vice versa. The size of ξ can vary from several tens of nm in metallic superconductors down to about 1 nm in the copper-oxide superconductors with high critical temperature T_c (HTS). The other length scale is set by the London penetration depth λ which describes the decay of an external magnetic field from the edge of a superconductor toward its interior, from which it is ultimately expelled.

The ratio between these two lengths bifurcates between two types of superconductors. While so-called type-I superconductors expel a magnetic field completely (Meissner effect), the more abundant and more widely used type-II superconductors let the magnetic field enter in quantized portions of the magnetic flux $\Phi_0 = h/(2e)$, where Φ_0 is termed the flux quantum, h and e are

Planck's constant and the elementary charge, respectively. These flux quanta in a superconductor are called fluxons or vortices; the latter name results from the fact that circular supercurrents in the surrounding material stabilize these flux quanta.

Coming back to the two characteristic lengths, it turns out that the so-called Ginzburg-Landau parameter, the ratio $\kappa = \lambda/\xi$, determines the type of a superconductor, with $\kappa \geq 1/\sqrt{2}$ leading to type-II superconductivity. Another important observation is the temperature dependence of $\xi(T) = \xi(0)(1 - T/T_c)^{-1/2}$, which implies a diverging enhancement of $\xi(T)$ from its minimal value $\xi(0)$ at $T = 0$ when T_c is approached. Ginzburg-Landau theory also predicts the same temperature dependence for $\lambda(T)$ and, thus, κ is temperature-independent near T_c .

In what follows, we will mainly discuss thin films of superconductors. In many situations, these can be considered three-dimensional (3D) materials, as long as the coherence length perpendicular to the surface is smaller than the film's thickness t_z . However, from the temperature dependence of $\xi(T)$ it is evident that close to T_c a transition to a two-dimensional (2D) behavior in very thin films might occur when $\xi(T) > t_z$.

Another issue becomes important for film thicknesses $t_z \lesssim \lambda(T)$. Then $\lambda(T)$ has to be replaced by an effective penetration depth (also called Pearl length) $\Lambda(T) = 2\lambda(T)^2/t_z$. Since $\lambda(T)$ (and $\Lambda(T)$, respectively) control the range of interactions between vortices, the relevant length scales can become macroscopic in very thin films. In any case, vortices separated by distances smaller than the (effective) penetration depth will behave as collective ensembles, occasionally termed 'vortex matter'. Note that in a magnetic field applied perpendicular to the surface of a thin superconductor, large demagnetization effects lead to a complete penetration of the magnetic flux and suppression of the Meissner screening.

Vortex physics is a fascinating and complex field of research, and only an introductory glimpse can be presented here to underpin the key issues related to nanostructured superconductors. For deeper insights, see the chapter by Brandt in this Encyclopedia and the review by Blatter et al. (1994).

Confining the superconducting condensate to the range of the length scales introduced above inevitably means that superconductors need to be structured to dimensions of a few μm and, primarily, to the nanoscale. The use of thin films and lateral nanostructuring allows one to substantially change many physical properties and create novel phenomena, absent in the pristine material. For example, the controlled manipulation of vortices by anchoring them to engineered defects, guiding their motion, or building artificial vortex matter plays a significant role. Engineered vortex systems are essential for creating model systems for basic research and enable to build almost dissipationless and ultrafast electronic devices based on vortex manipulation, the so-called fluxonics.

Taking advantage of Josephson effects in weakly-coupled superconductors requires barriers of only a few nm in width. The Josephson junction is the central building block for sensitive magnetic field sensors, rapid single flux quantum logic circuits, THz frequency generators, and, last but not least, superconducting quantum computing.

This chapter focuses on the nanostructuring of HTS that offer easy operation using cryocoolers or liquid nitrogen. However, the brittle nature and complex crystallographic structures of HTS make the fabrication of nanopatterns a problematic endeavor and call for new techniques. Many of these concepts have been developed since the first edition of this Encyclopedia. For a detailed overview of nanostructured metallic superconductors, the reader is referred to the book of Moshchalkov and Fritzsche (2011).

Nanofabrication techniques

Lithography and ion-beam milling

The standard techniques for nanopatterning of superconductor structures focus on thin-film processing. One of the most commonly used methods is photo- or electron-beam lithography, which is well known for the fabrication of semiconductor devices. After growing thin films on a suitable substrate and depositing a photoresist layer on top, the planar structures are defined by illuminating the photoresist through a mask or directly processing it with an electron-beam (e-beam) writer. While the wavelength of the light limits the former method, e-beam lithography can provide resolutions at the order of 10 nm but is a slow sequential technique.

Unfortunately, the subsequent etching processes of both photoresist and the superconductor result in significant degradation of resolution. Another issue is that etching artifacts, such as underetching below the photoresist layer, progressively limit resolution as the thickness of the superconducting film increases. Thus, patterns in metallic superconductors are generally reported with lateral structures on the order of 100 nm. For example, a vibrant application is the fabrication of single photon detectors (Gol'tsman et al., 2001) that commonly consist of few-nm thick NbN or NbTiN films patterned to long stripes, folded into meandering patterns to increase the active area (Hadfield, 2009). The above limitations are of particular importance for the reproducible fabrication of constriction-type Josephson junctions (Dayem bridges), for which a resolution of a few nanometers would be required.

For HTS, the situation is even more complicated because they are brittle and have a complex crystallographic structure. Lithographic techniques combined with etching steps have been successfully applied to create patterns with several hundred nanometers features sizes (Castellanos et al., 1997). The combination of e-beam lithography followed by argon-ion milling allowed the production of patterns with a minimum line width of 25 nm (Sochnikov et al., 2010). Since this is still too large to fabricate Josephson junctions directly, alternative fabrication methods, such as growing the thin film over a step-edge in the substrate, must be employed (Tafari and Kirtley, 2005).

Electromigration

An elegant way to further narrow the cross-section of superconductor bridges fabricated by conventional lithography is based on electromigration. This usually undesirable process, combining a local temperature rise and a high electric field, leads to a displacement of atoms from their original crystal-lattice positions. Closed-loop controlled electromigration, however, can avoid

adverse effects. With the gradual reduction of the cross-section of aluminum constrictions to $\lesssim 150 \text{ nm}^2$, a geometry-induced transition from thermally-assisted phase slips to quantum phase slips has been reported (Baumans et al., 2016). Other applications of electromigration include the tuning of Nb superconducting quantum interference devices (SQUIDS) (Collienne et al., 2021) and the controlled migration of oxygen atoms in $\text{YBa}_2\text{Cu}_3\text{O}_7$ (YBCO) bridges (Marinković et al., 2020).

Templating strategies

In bottom-up fabrication methods, the nanostructures are already predefined during the growth process. Since patterning the substrate material is often less challenging, several methods have been developed that take advantage of the controlled imperfection in the substrate to introduce the desired structures into the superconductor. One example is the self-organized growth of highly ordered porous alumina, a membrane-like system consisting of triangular arrays of pores. A superconducting Nb thin film deposited directly on the alumina template with a pore spacing of 50 nm acts as a nanoscale array for vortex pinning (Vinckx et al., 2007).

Nanowires of metallic superconductors less than 10 nm in diameter and up to 1 μm in length can be fabricated by ‘molecular templating’ (Bezryadin et al., 2000). After a freestanding carbon nanotube is placed over a narrow and deep slit in a Si substrate, a superconductor such as MoGe is sputtered onto the entire arrangement. The resulting layer consists of the electrodes connected by the nanowire, which are all made of the same material and thus have excellent contact resistances. Subsequently, the properties of the nanowire can be further fine-tuned in a transmission electron microscope or by applying voltage pulses.

Another technique uses vicinally cut substrates with a periodic nanoscale step structure of the clean substrate surface. YBCO films grow on such substrates in a roof-tile-like arrangement of the copper-oxide layers by self-assembly. The morphology and microstructure of such vicinal films strongly depend on the miscut angle of the SrTiO_3 substrate and the thickness of the on-top grown YBCO (Haage et al., 1997; Pedarnig et al., 2002), $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_8$ (Durrell et al., 2000), and $\text{Hg}_{1-x}\text{Re}_x\text{Ba}_2\text{CaCu}_2\text{O}_{6+\delta}$ (Re: rare earth element) (Yun et al., 2000) films. The linear arrangement of dislocations resulting from the step structure in YBCO leads to an exceptionally high critical current density. Moreover, symmetry breaking in such vicinal films also allows experimental access to out-of-plane properties of HTS, such as resistivity, Hall effect (Heine et al., 2021), photoconductivity (Markowitsch et al., 1997), and channeling of vortex strings along the *ab*-plane (Berghuis et al., 1997).

Strategies based on substrate modification are very versatile. Nanostructures can be deposited on the substrate prior to the deposition of a superconductor film to modify its structural and superconducting properties. A variety of interactions can be tailored with thickness modulation of the superconductor by insulating dots, proximity effects caused by metallic dots, or magnetic interactions with ferromagnetic dot arrays that interact with the vortex lattice in the superconductor (Martin et al., 1997).

Ion-induced nanostructures

The previously discussed patterning techniques have several disadvantages, especially when applied to HTS. First, all methods that remove material result in open side faces of the HTS, allowing the relatively mobile oxygen ions to escape from the crystallographic framework and thus lowering the oxygen content. In most cases, this leads to a degradation of the superconducting properties. On the other hand, the brittle nature of HTS limits the stability of the remaining material structures, making it challenging to achieve sub- μm resolution.

Irradiation of HTS with electrons, protons, and light or heavy ions provides an alternative route to modify the properties of HTS while leaving the surface of the material nearly intact. Before going into further details, a brief account of the limiting parameters is in order. A first consideration concerns the penetration range of irradiation. Only neutrons and high-energy ions can penetrate deeply enough into bulk materials (Weber, 2003). Irradiation with swift heavy ions produces columnar tracks of a few nm diameters in the HTS. The crystallographic structure is destroyed, and a non-superconducting amorphous channel remains (Civale, 1997). Such a columnar defect with a diameter similar to the in-plane coherence length is ideal for blocking the motion of vortices. This enhanced pinning of vortices leads to a higher critical current. These disordered arrangements of line-shaped pinning centers are not only very important for applications but have also triggered the theoretical and experimental study of novel phases of vortex matter, such as the vortex (Fisher et al., 1991) and Bose (Nelson and Vinokur, 1993) glasses.

A more subtle method of tailoring superconducting properties is to create point defects while leaving the crystallographic framework intact. They can be produced by irradiation with electrons, protons, or light ions. Point defects are imperfections at the atomic level that occur when the energy transfer from the incident particle to the crystal is on the order of the energy required to form vacancies. At energies up to a few MeV, the incident particle collides with and displaces a nucleus, eventually creating a collisional cascade that propagates through the material. The tradeoff in the choice of parameters stems from the fact that lighter particles, such as electrons, require extremely high fluence to achieve any appreciable change of the superconducting properties. In contrast, heavier particles have limited penetration depths and more significant scattering of the collisional cascades (Lang and Pedarnig, 2010).

A suitable candidate for the controlled fabrication of point defects in thin films of the most commonly used HTS, YBCO, are He^+ ions of moderate energy. The superconducting properties are tailored by displacing mainly oxygen atoms, which are more loosely bound than the other atomic species, with binding energies of 1... 2 eV for the chain atoms O1 and about 8 eV for the O2/O3 atoms in the CuO_2 planes, as shown in Fig. 1a. Their displacement creates Frenkel defects at interstitial positions (Gray et al., 2022) outlined in Fig. 1b, leading to a controllable decrease (Sefrioui et al., 2001) or complete suppression of T_c (Lang and Pedarnig, 2010), depending on the ion fluence. Since the charge transfer from the displaced atoms is still operational, Frenkel defects do not lead to a significant change in the carrier density.

Another process is responsible for reducing T_c : In classical superconductors with s-wave symmetry of the superconducting gap, the introduction of point defects has little effect on T_c and is even used technically to improve the critical current. In contrast, the anisotropic *d*-wave nature of the gap in HTS makes it susceptible to tiny defects that reduce not only the normal-state conductivity and carrier mobility but also T_c (Lang and Pedarnig, 2010).

However, a uniform statistical distribution of point defects is not very helpful. By focusing the ion beam before it hits the surface of the HTS film, one can create nearly cylindrical domains populated with point defects. These columnar defects (CDs) form a landscape where superconductivity is locally suppressed. Lateral modulation of ion fluence can be achieved mainly by two different methods outlined in Fig. 2.

Masked ion irradiation of thin films

An extensive array of multiple ion beams can be created by masking a wide-field collinear ion beam, which is commonly available with ion implanters, as schematically shown in Fig. 2a. An HTS film, thinner than the ion's penetration depth, is fabricated on a suitable substrate. The mask protects selected areas of the HTS film from irradiation and exposes the other sample parts to

Fig. 2 Two different methods for patterning a YBCO film by He^+ ion irradiation: (a) Ion beam patterning through a stencil mask produces a large number of columnar defects in a single step. The dark areas indicate the defect-rich, non-superconducting nanocylinders. (b) Irradiation with a slightly defocused beam from a helium-ion microscope produces tailored columnar defect patterns by scanning the beam across the sample surface. Adapted from Aichner B, Mletschnig KL, Müller B, Karrer M, Dosmailov M, Pedarnig JD, Kleiner R, Koelle D, Lang W (2020) Angular magnetic-field dependence of vortex matching in pinning lattices fabricated by focused or masked helium ion beam irradiation of superconducting $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ thin films. *Low Temperature Physics* 46: 331–337. <https://doi.org/10.1063/1.5000863>. Fiz. Nizk. Temp. 46: 402–409.

irradiation. While the former remain superconducting, the T_c of the latter is reduced or suppressed depending on the applied ion energy and fluence. Notably, the collision cascades widen due to the straggling of ion trajectories within the HTS so that the mask patterns become blurred with increasing depth. As a result, the lateral resolution is typically limited to about 10 nm, as indicated by simulations with 75 keV He^+ irradiation (Haag et al., 2014).

Different techniques were used to create the mask. Either a photoresist layer was deposited on the HTS and processed with standard UV (Kahlmann et al., 1998), e-beam, (Swiecicki et al., 2012), or focused ion beam (Katz et al., 2000) lithography, then etched and used as the mask, or a metal layer was deposited directly on the YBCO film and then patterned by ion beam milling (Kang et al., 2002). Alternatively, a Si stencil mask is fabricated and mounted at a small distance from the superconductor film (Lang et al., 2006). This method allows the mask to be reused, does not require the multiple processing steps associated with photoresist, and avoids potential surface degradation.

The main advantage of masking techniques is the parallel processing of many structures. Shortcomings are the resolution limitations resulting from the preparation of the mask, and in the case of freestanding masks, there are geometrical limitations, e.g., disconnected blocking elements are not possible.

Focused ion beam modification of thin films

In contrast to conventional focused ion beam (FIB) machines, which use Ga to ablate the material, devices for focused ion irradiation with light ions have only recently become available. The helium ion microscope (HIM) (Ward et al., 2006) combines scanning focused ion beam sources for He^+ and Ne^+ ions and imaging via secondary electron detection. The HIM consists of a gas-field ion source that emits ions from a tip containing only three atoms (the trimer), electrostatic ion optics to focus and trim the beam, and a deflection system that moves the beam across the sample stage with optional blanking (Fig. 3). Because of the high source brightness of the trimer and the short de Broglie wavelength of He^+ ions, an image resolution better than 0.5 nm and an unprecedented depth of focus can be achieved (Hlawacek and Götzhäuser, 2016).

Using a He or Ne beam instead of the conventional Ga—FIB technique avoids contamination of the target material by Ga ions and achieves higher lateral resolution. For example, nanopores as small as 1.3 nm in diameter have been fabricated in 1 nm-thick carbon nanomembranes (Emmrich et al., 2016). As initial applications in HTS, thin barriers of insulating material, written across prepatterned YBCO microbridges with the focused ion beam, form Josephson junctions (Cybart et al., 2015), and ultradense arrays of CDs build a complex pinning landscape for vortices (Aichner et al., 2019). At the time of writing, hexagonal arrays of CDs with spacings as small as 20 nm had been fabricated in YBCO thin films (Karrer et al., 2022).

The use of He—FIB relies on the weak bonding of oxygen in HTS and cannot be employed in the same way for other superconductors. However, a focused Ne beam offers a compromise between Ga—FIB and He—FIB for direct milling of metallic

Fig. 3 Schematic drawing of the helium ion microscope used for direct-writing patterns of locally suppressed superconductivity. (Courtesy of Bernd Aichner, University of Vienna).

superconductors. This has been demonstrated, for example, for patterning constrictions in NbN films to form nanowires (Burnett et al., 2017).

Other techniques for growing superconductor nanostructures using focused electron and ion beams are discussed in the chapter by Córdoba, and the properties of superconducting microtubes and nanohelices are examined by Fomin (2020).

Properties of nanopatterned superconductors

Nanostructuring of superconductors enables selective tailoring of the superconducting condensate on length scales smaller than the London penetration depth, mainly by creating lateral structures. Such patterns allow controlled interaction of vortices, their manipulation, as well as tunneling effects between two superconducting condensates weakly coupled by a small non-superconducting interlayer. Some of these applications are described below.

Vortex pinning arrays

Lateral nanostructuring of superconducting films with regular arrays of CDs allows the creation of artificial pinning landscapes that lead to commensurability effects with the flux line lattice. This occurs at the so-called matching fields $B_k = k\Phi_0/A$, where k is an integer number of pinning sites (or a rational number of vortices) in the unit cell of the pinning array of area A . For square lattices $A = a^2$ and for hexagonal patterns $A = \sqrt{3}a^2/2$ with a the nearest neighbor spacing of the CDs.

The number of flux quanta that can be trapped inside a cylindrical hole or in a non-superconducting pinning site depends on its diameter r_p and the coherence length $\xi(T)$ of the superconductor. For anisotropic layered materials such as HTS, the in-plane coherence length $\xi_{ab}(T)$ is relevant. Once all pinning sites are filled by one flux quantum, the formation of multi-quantum vortices becomes energetically favorable when r_p exceeds a certain critical radius (Buzdin, 1993). The saturation number of trapped flux quanta can be estimated by $n_s \simeq r_p/2\xi(T)$ (Buzdin and Feinberg, 1996).

A special situation arises for blind holes in a superconductor, i.e., holes that do not entirely penetrate the material. The remaining superconducting bottom layer carries the screening currents of individual vortices trapped in the blind hole. Although several flux quanta are trapped in the blind hole, individual vortices can still be made visible (Bezryadin et al., 1996).

Multi-quantum vortices are a phenomenon that occurs only in nanostructured superconductors and does not exist in pure homogeneous superconductors. Conversely, when small pinning sites cannot accommodate the total flux, the excess flux is forced to enter the material via interstitial vortices. The various commensurability effects in a pinning landscape for different magnetic fields applied orthogonally to the film surface are illustrated in Fig. 4, which is based on experimental results by Lorentz microscopy of vortices in a Pb film patterned with a square array of tiny blind holes (Harada et al., 1996). For filling factors $k < 1$, the flux quanta are arranged in a superlattice with respect to the pinning array; for $k = 1$, each hole is filled with precisely one flux quantum, and for $k = 2$, the excess flux is taken up by interstitial vortices.

The commensurability effects manifest themselves in various physical parameters, such as steps in the magnetization loops and peaks in the critical current as indicators of enhanced pinning forces. Minima in the resistance versus magnetic field curves point to commensurability effects of moving vortex ensembles.

Fig. 5 shows an example of the dramatic change of the magnetization loop $M(H)$ after perforating a 60 nm-thick WGe film with a square array of holes 340 nm in diameter and 1 μm apart (Moshchalkov et al., 1996). The area of the $M(H)$ loop in the perforated film is massively increased due to the holes, which act as artificial pinning centers. Distinct cusps in the loop appear at the matching fields $B_k = k \times 2.07$ mT, indicating the trapping of multi-quantum vortices. The staircase-like reduction of $M(H)$ with increasing field

results from the few excess vortices that appear after filling the holes with k vortices. These are initially repelled by the trapped vortices and can move in the interstitial region with higher mobility. As soon as the number of the excess vortices is large enough, they fill up the holes to $k + 1$ multi-quanta vortices.

When the diameter of holes in a superconducting film is increased to a size close to their spacing, a gradual change from a pinning lattice to a multiply connected network of superconducting wires takes place. Such wire networks exhibit modulation of the critical temperature with the magnetic flux, the Little-Parks effect (Parks and Little, 1964). A further enlargement of the holes leads to the formation of disconnected superconducting islands with intriguing properties, described in detail in the chapter by Poccia.

In HTS, commensurability effects can be preferably detected by electric transport measurements, e.g., in YBCO thin films patterned with a square lattice of holes (Castellanos et al., 1997). However, the situation is more complicated because YBCO thin films have strong inherent pinning by crystallographic micro-twinning, screw dislocations, and other intrinsic defects.

The competition between pinning on these inherent defects and trapping vortices on engineered pinning sites requires that the latter be relatively dense, with a spacing of $\lesssim 300$ nm. Such a resolution is hard to achieve by lithographic methods. Still, it is in reach of masked or focused ion beam modification, which can raise the magnitude of the matching fields into the range of several tesla.

A demonstration of vortex commensurability effects at high magnetic fields is shown in Fig. 6a in a YBCO film with a dense hexagonal pinning lattice with $a = 30$ nm spacing. Since a is much smaller than the Pearl length $\Lambda(0)$, peaks in the critical current caused by enhanced pinning of vortices can be observed at temperatures far below the superconducting transition. Matching effects of mobile vortices at higher temperatures can be traced as dips in the resistivity, as shown in Fig. 6b. Moreover, the preferential trapping of vortices within the CDs can be confirmed by tilting the applied magnetic field away from the axes of the CDs by an angle α , as illustrated in the inset of Fig. 6b. Then, the position of the matching dips scales with the magnetic field component parallel to the axes of the CDs. These effects prevail up to high tilt angles of $\alpha \leq 70^\circ$ (Aichner et al., 2020).

Complex pinning landscapes

When moving from pinning lattices with hexagonal or square arrangements to more complex periodic or aperiodic tilings, numerous unusual phenomena occur. Some examples are shown in Fig. 7. Such patterns have been studied theoretically (Laguna et al., 2001; Misko et al., 2005; Reichhardt and Olson Reichhardt, 2007; Misko and Nori, 2012) and experimentally in metallic superconductors with holes (Kemmler et al., 2006; Misko et al., 2010; Bothner et al., 2014) and magnetic dots (Villegas et al., 2006; Silhanek et al., 2006; Kramer et al., 2009), like Penrose (Kemmler et al., 2006; Misko et al., 2010), honeycomb (Welp et al., 2002; Latimer et al., 2012) and Kagomé (Cuppens et al., 2011) lattices and artificial vortex ice arrangements in geometrically frustrated pinning lattices (Libál et al., 2009; Latimer et al., 2013; Xue et al., 2018).

In HTS, such studies are more challenging and could be hampered by strong intrinsic pinning. However, complex pinning structures lead to competition between the pinning forces at the CDs and the elastic energy of the vortex lattice, attempting to restore the natural hexagonal vortex configuration of a clean superconductor. For example, pinning landscapes that force the magnetic flux quanta in an ice-like flux arrangement due to a geometrically frustrated energy landscape can transition to a periodic flux distribution at higher temperatures, thawing the vortex ice (Trastoy et al., 2014).

Fig. 6 Vortex commensurability effects in YBCO thin films with an array of columnar defects created by focused He^+ ion beam irradiation. (a) Critical current at 5 K as a function of the applied magnetic field of a thin YBCO film with a hexagonal pattern of columnar defects spaced 30 nm apart. At the first matching field $B_1 = 2.65$ T, a peak of the critical current is caused by strong commensurability effects. Another peak occurs when two vortices are trapped in the pins. The inset shows the superconducting transition in zero magnetic field. (b) Angular dependence of vortex matching effects in the resistance of a YBCO thin film with a square lattice of 200 nm spaced columnar defects: The resistance is plotted as a function of the applied field component along the normal of the film surface $B_{||} = B_a \cos \alpha$ for different values of α . For $\alpha > 0^\circ$, the curves are shifted by multiples of 0.1 m Ω for better visibility. The inset shows a sketch of the experimental situation. (a) Adapted from Backmeister L, Aichner B, Karrer M, Wurster K, Kleiner R, Goldobin E, Koelle D, Lang W (2022) Ordered Bose glass of vortices in superconducting $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ thin films with a periodic pin lattice created by focused helium ion irradiation. *Nanomaterials*, submitted; (b) Reprinted with permission from Aichner B, Mletschnig KL, Müller B, Karrer M, Dosmailov M, Pedarnig JD, Kleiner R, Koelle D, Lang W (2020) Angular magnetic-field dependence of vortex matching in pinning lattices fabricated by focused or masked helium ion beam irradiation of superconducting $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ thin films. *Low Temperature Physics* 46: 331–337. <https://doi.org/10.1063/10.0000863>. Fiz. Nizk. Temp. 46, 402–409.

Fig. 7 Examples of complex pinning landscapes. Bright circles indicate pinning centers (holes or columnar defects), and solid blue lines the unit cell of a periodic lattice. (a) The Kagomé lattice is related to the hexagonal lattice. The latter can be recovered if one pin is added to each void's center. (b) Vortex-ice lattice: four pairs of pins (indicated by orange ellipses) meet at each vertex of a square lattice. (c) The aperiodic Penrose tiling. The dashed blue lines indicate the five-fold symmetry.

Another example of a complex pinning landscape, the quasi-Kagomé tiling, shows an unconventional commensurability effect. At elevated temperatures, all pins are occupied by vortices, and one interstitial vortex is magnetically caged in each void of the lattice. The balance between the pinning forces exerted by the CDs and the vortex caging potential can be tuned with the temperature (Aichner et al., 2019). Controlled manipulation of such magnetically confined vortices can pave the way toward fluxonic applications of HTS.

Vortex ratchets and flux diodes

By introducing spatial asymmetry into the pinning arrays, many exciting effects emerge. In general, the idea of a 'Brownian motor' refers to Brownian motion in combination with an unbiased external input signal that can induce submicron directional movement of particles (Hänggi and Marchesoni, 2009). A well-known example is the directional propagation of vortices in an appropriately structured superconductor, usually referred to as a 'vortex ratchet' or 'fluxon pump' (Wambaugh et al., 1999). It provides a flexible and well-controlled model system for studying stochastic transport processes and can operate up to THz frequencies (Hastings et al., 2003).

Vortex ratchets can be realized by various concepts, such as 2D asymmetric channel walls. They can be further extended to design 'fluxon optics' devices, concave/convex fluxon lenses that disperse/concentrate fluxons in nanodevices (Wambaugh et al., 1999). Also, asymmetric potential barriers, e.g., in the form of square arrays of triangular pinning centers (Villegas et al., 2003), double-well traps (Van de Vondel et al., 2005), or an asymmetric arrangement of symmetric traps, (Wördenweber et al., 2004; Perez de Lara et al., 2010) lead to vortex rectification effects.

Interestingly, ratchet effects are proposed in binary particle mixtures without needing an asymmetric substrate (Savel'ev and Nori, 2002). For example, in layered superconductors, such as HTS, an inclination of the magnetic field from the c axis leads to a mixture of pancake vortices and Josephson strings. This hybrid vortex system exhibits ratchet effects with time asymmetric drives (Cole et al., 2006).

Finally, understanding ratchet effects in different systems is an exciting topic. Studying these effects with fluxons provides a more direct and controllable experimental approach than for most other systems. Ultimately, these investigations may pave the way for cellular automata as an alternative concept (Hastings et al., 2003; Milošević et al., 2007) for performing clocked logic operations on discrete particles. Moreover, vortex ratchets are proposed (Lee et al., 1999) as an effective method for evacuating magnetic flux from superconducting devices, where inadvertently trapped flux might be detrimental to operation, such as in SQUID magnetic sensors.

A related concept is the lossless superconducting diode. This electronic device has zero resistance only for one direction of applied current and is desirable for building electronic circuits with ultra-low power consumption. It can be realized as a superconducting film patterned with a conformal array of nanoscale holes that breaks spatial inversion symmetry (Lyu et al., 2021). A conformal array is a structure resulting from the transformation of a uniform hexagonal pinning array that retains the sixfold order of the original lattice but exhibits a gradient in site density (Reichhardt et al., 2015).

Guided vortex motion

Controlled vortex motion along a predefined path can be achieved by patterning narrow channels or parallel rows of defects into a superconductor. This so-called 'guided vortex motion' results from an easy track in which vortex pinning is reduced (Dobrovolskiy et al., 2016), a row of holes (Silhanek et al., 2010), or, in HTS, the suppression of superconductivity by heavy-ion irradiation (Laviano et al., 2010). Guided vortex motion can be detected by the deflection of vortices from their trajectory imposed by the Lorentz force. This leads to a pronounced transverse voltage (Wördenweber et al., 2004) that can be distinguished from the conventional Hall effect by its even symmetry with respect to the reversal of the magnetic field. Guided vortex motion also plays an important role in experiments where vortices are accelerated to high velocities, as discussed in the chapter by Dobrovolskiy.

Josephson junctions

A ubiquitous need for nanostructuring of superconductors arises from the fabrication of Josephson junctions (JJs), where two superconducting systems are separated by an insulating or metallic barrier of a few nm thickness or by another weak coupling link. It is crucial that the Josephson weak links are stable and can be reproducibly fabricated. While for metallic superconductors, the industrial fabrication of circuits based on JJs has been established for many years (Likharev, 2012), the fabrication of JJs in HTS is much more challenging. It is still in the phase of cumulative progress.

JJs consisting exclusively of HTS materials have been produced by introducing a crystallographic fault (break junctions), by using a grain boundary between different crystallites, by growing thin HTS films over a substrate step, by narrow constrictions (Dayem bridges), or by multilayers forcing the current along the c -axis (Koelle et al., 1999). Here we restrict ourselves to discussing JJs in HTS produced by masked or focused ion irradiation. A general account of this subject can be found in the chapter by Tafuri.

Several attempts have been made to fabricate JJs by irradiation techniques. Initially, direct writing of narrow lines with an electron beam across a pre-patterned YBCO bridge in a scanning electron microscope resulted in somewhat unstable JJs and required high electron doses. Later, creating a weak link in YBCO bridges by implanting oxygen ions through a lithographically defined mask led to superconducting-normal-superconducting (SNS) JJs with resistively shunted junction (RSJ) properties (Tinchev, 1996; Kahlmann et al., 1998; Bergeal et al., 2005). However, the minimum width of the mask structures of about 20 nm and the inevitable straggle of ion collision cascades in the YBCO film set resolution limits and prevent fabrication of superconductor-insulator-superconductor (SIS) junctions, which would be the ultimate goal.

A similar technique, but using 200 keV Ne^+ ions allows complete penetration of the ions through the YBCO film, avoiding implantation and limiting the intended damage to the creation of point defects (Katz et al., 1998). This technique can be scaled up to integrating many JJs in a 2D series-parallel array; 15,820 (28×565) JJs have been demonstrated (Cybart et al., 2009).

Focused He^+ ion irradiation in a HIM took the fabrication of JJs one step further. Tunnel junctions can be directly written with the focused He -ion beam into YBCO films, as illustrated in Fig. 8. The properties of the barrier are controlled by varying the irradiation dose. With this technique, SIS junction can also be realized (Cybart et al., 2014). Scanning transmission electron analysis shows that the amorphous tracks created by 1500 He^+/nm have a lateral extension of 4 nm, while no destruction of the crystallographic structure is observed at lower fluence. Nevertheless, the devices produced with the lower doses show an explicit JJ behavior (Müller et al., 2019).

Fig. 8 (a) Schematic illustration of a Josephson junction fabricated by focused He^+ ion irradiation in a helium ion microscope. (b) Scanning electron image of the junction (visible as a thin dark line) patterned with a fluence of 600 ions/nm. Figures reprinted with permission from Müller B, Karrer M, Limberger F, Becker M, Schröppel B, Burkhardt CJ, Kleiner R, Goldobin E and Koelle D (2019) *Physical Review Applied* 11: 044082. Copyright 2019 by the American Physical Society.

The He—FIB technique can, in principle, be applied to other HTS, as demonstrated for $\text{La}_{1.84}\text{Sr}_{0.16}\text{CuO}_4$ (Gozar et al., 2017) and other superconducting materials such as MgB_2 (Kasaei et al., 2018). The versatility of directly written structures and JJs provides a tremendous advantage in fabricating superconducting quantum interference devices (Müller et al., 2019), JJ arrays (LeFebvre et al., 2019), and even more complex devices on the same substrate for various applications.

Conclusion

In this chapter, we have outlined various methods for fabricating nanostructured superconductors. While established lithographic and ion-milling techniques enable the patterning of metallic superconductors, novel techniques are required for nanoscale structures in copper-oxide superconductors. For example, focused He^+ -ion beam irradiation creates columnar channels of point defects and can be used to create vortex pinning landscapes and weak links for Josephson junctions. Superconducting nanostructures are already indispensable for many applications and will bring further significant advances to superconducting electronics, from fluxonics to ultra-high sensitivity magnetometers and many others. Beyond that, the dawning age of superconducting quantum computing depends heavily on precise and reproducible nanostructured circuits on a large scale.

Abstract

Kondo effect occurs in electron transport through a quantum dot when the number of electrons in the quantum dot is odd and at low temperatures. The conductance increases due to the resonant tunneling through the Kondo peak emerging at the Fermi energy. Two Coulomb peaks gradually grow and shift to their center as the temperature decreases. Then at the lowest temperature they merge into a single plateau, the Kondo plateau. The change of conductance can be explained by the Kondo temperature which is a function of the gate voltage.

Key points

- Kondo effects take place in electron transport through a quantum dot at low temperatures
- The Kondo effect appears as conductance enhancement between the Coulomb peaks where the number of electrons in a quantum dot is odd
- The conductance shows the Kondo plateau at the absolute zero temperature
- How does the conductance change from the Coulomb peaks to the Kondo plateau when temperature decreases?
- Change of conductance is explained by the Kondo temperature
- Kondo temperature is a function of the voltage applied to a gate electrode nearby a quantum dot

Introduction

Electron transport measurement through a quantum dot is performed with left and right leads attached near the quantum dot. The schematic structure of the quantum dot for the electron transport is shown in Fig. 1.

In most cases, the electron transport through the quantum dot is forbidden because of the strong Coulomb repulsion between the electrons in the quantum dot, which is known as the Coulomb blockade.

The electrical potential in the quantum dot can be controlled by applying a voltage to a gate electrode nearby the quantum dot. When the gate voltage continuously changes, the number of electrons in the quantum dot $\langle n_d \rangle$ changes by exchanging the electrons between the quantum dot and the leads. Because of the strong Coulomb repulsion, $\langle n_d \rangle$ changes one by one as shown in Fig. 2A. Electrons can transport through the quantum dot only when $\langle n_d \rangle$ changes. The linear response conductance as a function of the gate voltage shows peaks. The peaks reflect the change of $\langle n_d \rangle$, as shown in Fig. 2. The peaks in the conductance are referred to as the Coulomb peaks.

At low temperatures the Kondo effect takes place as a strikingly remarkable effect in the electron transport through the quantum dot as was first theoretically pointed out (Glazman and Raikh, 1988; Ng and Lee, 1988; Kawabata, 1991). In the gate voltage region where there exist an odd number of electrons in the quantum dot, a local spin moment $S = 1/2$ appears in the quantum dot from an unpaired electron. The quantum dot with an odd number of electrons behaves like a magnetic impurity. The local spin moment interacts with the electrons in the left and right leads. The coupling between the local spin and the electrons in the leads becomes stronger at lower temperatures. The conductance is largely enhanced because of the strong coupling, even though the number of electrons in the quantum dot is fixed, that is, the quantum dot is in the Coulomb blockade region. This is the most typical Kondo effect in the quantum dot. The conductance plateau caused by the Kondo effect is referred to as the Kondo plateau, as shown in Fig. 2.

Fig. 1 Schematics of the quantum dot structure for electron transport.

Fig. 2 (A) The number of electrons in the quantum dot as a function of the gate voltage, and schematics of electron occupation in the quantum dot in each gate voltage region. Local spin moment from an unpaired electron appears when the number of electrons is odd. (B) Linear response conductance as a function of the gate voltage. Conductance shows Coulomb peaks reflecting the change of number of electrons in the quantum dot. The Kondo effect takes place at low temperatures in the gate voltage region where the number of electrons in the quantum dot is odd. As the temperature decreases, the conductance changes from the Coulomb peaks to the Kondo plateau.

A brief introduction of the Kondo effect in the quantum dot similar to this section can be found in the book by Kondo (2012). The later part of this chapter will address how the conductance changes from the Coulomb peaks to the Kondo plateau when the temperature decreases.

This chapter is organized as follows. First, we formulate the quantum dot with the simplest model. The model can be mapped onto the Anderson model studied for the Kondo effect in a magnetic impurity in a metal. We overview the properties of the Anderson model from the viewpoint of the quantum dot. We then explain how the conductance changes from the Coulomb peaks to the Kondo plateau. In the summary, we introduce some other topics that are not discussed in the main part of this chapter.

Formulations for the quantum dot

A model of the quantum dot

Let us consider the simplest model including the Coulomb blockade and the Kondo effect for the electron transport through the quantum dot. The model contains only a single spin degenerate orbital in the quantum dot. The model is given by the following Hamiltonian,

$$H = H_1 + H_d + H_{1-d}, \quad (1)$$

$$H_l = \sum_{\ell=L,R} \sum_{k\sigma} \varepsilon_k c_{lk\sigma}^\dagger c_{lk\sigma} \quad (2)$$

$$H_d = \sum_{\sigma} \varepsilon_d n_{d\sigma} + U n_{d\uparrow} n_{d\downarrow}, \quad (3)$$

$$H_{l-d} = \sum_{\ell=L,R} \sum_{k\sigma} V_{\ell} d_{\sigma}^\dagger c_{lk\sigma} + \text{h.c.} \quad (4)$$

H_l represents the electrons in the left ($\ell = L$) and right ($\ell = R$) leads. H_d represents the electrons in the quantum dot. H_{l-d} represents the electron tunneling between the leads and the quantum dot. $c_{lk\sigma}^\dagger$ is the creation operator of the electron of state k with spin $\sigma (= \uparrow, \downarrow)$ in the ℓ -lead, and ε_k is the energy for the electron of state k . $d_{\sigma}^\dagger$ is the creation operator of the electron in the quantum dot with spin σ . $n_{d\sigma} = d_{\sigma}^\dagger d_{\sigma}$ is the number operator of the quantum dot state. The energy of the orbital in the quantum dot, ε_d , can be controlled by the gate voltage. U is the Coulomb interaction between the electrons in the quantum dot. This model covers the region in $0 \leq \langle n_d \rangle \leq 2$, where $\langle n_d \rangle = \sum_{\sigma} \langle n_{d\sigma} \rangle$ is the expectation value of the number of electrons in the quantum dot. V_{ℓ} is the tunnel matrix element between the orbital in the quantum dot and the k state in the ℓ -lead, and it is assumed to be independent of k . V_{ℓ} can also be controlled in the setup of the quantum dot: for instance, by applying the split gate voltage between the quantum dot and the leads.

Linear response conductance

In general, the conductance for a low bias voltage between the left and right leads is expressed by the correlation function of the current $\lambda \dot{N}_L - (1 - \lambda) \dot{N}_R$ in the linear response theory, where $\dot{N}_{\ell}$ is the time differentiation of the electron number in the ℓ -lead and λ is a weight. For the present single orbital model, the conductance can be expressed in the convenient expression,

$$G = \frac{2e^2}{h} \alpha \int d\varepsilon \left(-\frac{\partial f}{\partial \varepsilon} \right) \pi \Gamma \rho_d(\varepsilon), \quad (5)$$

where $\rho_d(\varepsilon)$ is the density of states of the quantum dot per spin, $f(\varepsilon) = 1/(e^{\beta(\varepsilon - \varepsilon_F)} + 1)$ is the Fermi distribution function, ε_F is the Fermi energy in the leads, and $\beta = 1/k_B T$ is the inverse of the temperature. In the later discussion, we set $k_B = 1$ and $\varepsilon_F = 0$. The tunnel coupling is parameterized by the width of the energy level of the quantum dot $\Gamma = \sum_{\ell} \Gamma_{\ell}$, where $\Gamma_{\ell} = \pi |V_{\ell}|^2 \rho_{\ell}$ and ρ_{ℓ} is the density of states in the ℓ -lead. The factor in Eq. (5),

$$\alpha \equiv \frac{\Gamma_L \Gamma_R}{[(\Gamma_L + \Gamma_R)/2]^2} \quad (6)$$

is caused by the asymmetry between Γ_L and Γ_R , and it has the maximum value $\alpha = 1$ for the symmetric coupling $\Gamma_L = \Gamma_R$.

A detailed theoretical background for this section can be found in the report by Izumida et al. (2001) and references therein. The formulation explained here was restricted to that related to the following discussion.

For the electron transport, several theoretical methods have been developed. For instance, the master equation approach treating the tunneling event semi-classically, is often utilized to explain the Coulomb blockade phenomena, as described in the book by Bruus and Flensberg (2004).

Anderson model for the Kondo problem

The model of the quantum dot is equivalent to the Anderson Hamiltonian which has been extensively studied for the Kondo problem on a magnetic impurity in a metal. The quantum dot corresponds to the magnetic impurity and the leads correspond to the metal. The equivalence of the models can be shown by the unitary transformation for the conduction electrons $s_k = (V_L c_{Lk\sigma} + V_R c_{Rk\sigma})/V$, where $V = \sqrt{|V_L|^2 + |V_R|^2}$ is the hybridization with the conduction electron states. Electronic states of the anti-symmetric combination $a_k = (V_L c_{Lk\sigma} - V_R c_{Rk\sigma})/V$ are disconnected to the orbital state in the quantum dot and can be discarded.

It is not easy to calculate the density of states even for such a simplified model. An analytical expression of the density of states is available for some limited cases as will be shown in this section. The detailed theoretical treatment on the Anderson model and related topics for a magnetic impurity in a metal can be found in the books by Yosida (1996), Hewson (1997), and Kondo (2012).

In the following subsections we shall consider some approximated cases, and overview the studies of the Kondo problem from the viewpoint of the Kondo effect in the quantum dot.

Isolated quantum dot approximation

Let us first consider the approximation $V_{\ell} = 0$, for which the quantum dot is isolated from the leads. The approximation corresponds to that is called the atomic limit in the study of the Anderson model. The density of states is given with the Dirac delta function as

$$\rho_d(\varepsilon) = \left(1 - \frac{\langle n_d \rangle}{2}\right) \delta(\varepsilon - \varepsilon_d) + \frac{\langle n_d \rangle}{2} \delta(\varepsilon - (\varepsilon_d + U)), \quad (7)$$

for the non-magnetic solution $\langle n_{d\uparrow} \rangle = \langle n_{d\downarrow} \rangle = \langle n_d \rangle / 2$.

The number of electrons in the quantum dot changes at $\varepsilon_d = 0$ and $\varepsilon_d + U = 0$ for the solution at $T = 0$. It is summarized as

$$\langle n_d \rangle = \begin{cases} 0 & \varepsilon_d > 0 \\ 1 & -U < \varepsilon_d < 0 \\ 2 & \varepsilon_d < -U \end{cases} \quad (8)$$

The density of states shows peaks at $\varepsilon = \varepsilon_d$ and $\varepsilon = \varepsilon_d + U$. Therefore, the conductance as a function of ε_d has peaks at $\varepsilon_d = 0$ and $\varepsilon_d = -U$ at which $\langle n_d \rangle$ changes. These peaks are the Coulomb peaks. The Coulomb blockade phenomena can be captured with the approximations treating the tunnel coupling perturbatively including the master equation method.

At low temperatures, the electron transport shows a remarkable difference from the Coulomb blockade in the region of $\langle n_d \rangle = 1$. This is the main topic of this chapter. In the next subsection, we shall discuss another approximation which can be extended to describe the phenomena with the Kondo effect at low temperatures.

Non-interacting approximation

For the non-interacting case $U = 0$, the problem is reduced to the single-particle problem. In this case the density of states is given by the Lorentzian function

$$\rho_d(\varepsilon) = \frac{1}{\pi} \frac{\Gamma}{(\varepsilon - \varepsilon_d)^2 + \Gamma^2}. \quad (9)$$

In this case we have the following relation between the density of states at the Fermi energy and the number of electrons in the dot at $T = 0$

$$\pi \Gamma \rho_d(0) = \sin^2 \left(\frac{\pi}{2} \langle n_d \rangle \right). \quad (10)$$

Therefore, the conductance is given by the number of electrons in the quantum dot as

$$G = \frac{2e^2}{h} \alpha \sin^2 \left(\frac{\pi}{2} \langle n_d \rangle \right). \quad (11)$$

This equation shows that the conductance has a maximum value $(2e^2/h)\alpha$ when $\langle n_d \rangle = 1$. The large conductance is due to the resonant tunneling through the energy level located at the Fermi energy $\varepsilon_d = \varepsilon_F$. Interestingly, the equation holds for the interacting case at low temperatures in which the system being the Fermi liquid, as described later.

Kondo problem for a magnetic impurity in a metal

As mentioned above, the Anderson model had been extensively investigated for the Kondo problem. Here we shall briefly overview these studies while focusing on the density of states.

A local spin moment appears due to the Coulomb interaction between the localized electrons. This local spin moment interacts with the conduction electrons via an exchange interaction $J = -V^2 \{1/|\varepsilon_d| + 1/(\varepsilon_d + U)\} < 0$. This is the s-d model which can be deduced from the Anderson model as its effective Hamiltonian via a transformation treating the hybridization term as perturbation.

As was shown by Kondo in 1964 with the s-d model, the scattering of the conduction electrons by the local spin moment has a term $\ln T$, which increases logarithmically when the temperature T is lowered, within the second order perturbation in J . The scattering T -matrix has a contribution $\ln |\varepsilon|$ and it is connected to the local Green function G_d as $T = VG_dV$. Then the logarithm corresponds to a resonance in the density of states $\rho_d(= -\text{Im } G_d/\pi)$ at the Fermi energy at low temperatures.

The perturbation calculation in J is not valid at low temperatures since the $\ln T$ divergence. The perturbation in J , namely the perturbation in V , describes the system for high temperatures $T \gg T_K$, where T_K is known as the Kondo temperature.

At low temperatures $T \ll T_K$ the local spin strongly couples to the conduction electrons and falls into a spin singlet state. The U -perturbation theory describes the Fermi liquid properties of the system at low temperatures. The density of states near the Fermi energy is approximately expressed by Eq. (9) where the parameters are replaced by the renormalized ones: $\varepsilon_d \rightarrow \tilde{\varepsilon}_d \sim 0$, $\Gamma \rightarrow \tilde{\Gamma} \sim T_K$. The density of states has a resonance peak referred to as the Kondo peak at the Fermi energy with the large value $\pi \Gamma \rho_d(0) = 1$ for $\langle n_d \rangle = 1$.

It is important for the Kondo effect in the quantum dot that Eq. (10) holds at low temperatures even for the interacting case. Then, as expressed in Eq. (11), the large value of the conductance for $\langle n_d \rangle = 1$ appears as the Kondo plateau. A natural question then is: how does the conductance change from the Coulomb peaks to the Kondo plateau as the temperature decreases?

Various approaches beyond the perturbation have been developed. The numerical renormalization group (NRG) method introduced by Wilson in 1975 successfully covers the crossover of the system state from magnetic at high temperatures to nonmagnetic at low temperatures. Later, an exact solution using the Bethe ansatz confirmed Wilson's calculation. The dynamical excitation spectra such as the density of states cannot be calculated via the Bethe ansatz. The NRG has been developed to calculate these quantities in the wide range of energy and temperature. It provides a powerful tool for the calculation of the Kondo systems. For the development of the NRG method see the review by Bulla et al. (2008).

Fig. 3 Local density of states $\pi\Gamma\rho_d(\omega)$ calculated by using the NRG method. The parameters are $\Gamma = 0.03\pi$ and $U = 1.0$. The temperatures are $T/T_K = 0$ (solid line), 0.35 (dashed line), 0.7 (dot-dashed line) and 1.4 (two-dots-dashed line), where $T_K = 3.34 \times 10^{-3}$. The constant conduction band from $-D$ to D is assumed and D is chosen as the energy unit. Reproduced with permission from Shimizu Y and Sakai O (1995) Computational Physics as a New Frontier in Condensed Matter Research, Study on the Excitation Spectra of the Strongly Correlated Electron Systems based on the Numerical Renormalization Group Method – Single Impurity and Infinite Dimensional Lattice Models–, 42–50. The Physical Society of Japan, 1995.). (c) 1995 The Physical Society of Japan.

We shall present the density of states calculated by the NRG in the next subsection.

Emergence of the Kondo peak

As mentioned in the previous subsection, the Kondo peak emerges when the temperature decreases. The Kondo peak plays an important role in the transport through the quantum dot. Here we shall show the density of states calculated by the NRG method.

Fig. 3 shows the calculated local density of states for the electron-hole symmetric case $\varepsilon_d + 2U = 0$ by Shimizu and Sakai (1995). This result clearly shows the expected behaviors from the discussion in the above subsections. The peaks around ε_d and $\varepsilon_d + U$ are originated from the charge excitation. The sharp and narrow peak at the Fermi energy is the Kondo peak. It is important to note that the intensity of the Kondo peak increases when the temperature decreases in the low temperatures $T < T_K$.

In the next section we will show how the conductance changes from the Coulomb peaks to the Kondo plateau when the temperature decreases.

Coulomb peaks to Kondo plateau

The emergence of the Kondo peak plays a significant effect, the resonance tunneling, in the quantum dot at low temperatures. We shall discuss how the conductance changes when the temperature decreases within the NRG calculation.

Fig. 4 shows the calculated conductance as a function of energy of the orbital in the quantum dot ε_d , $G(\varepsilon_d)$, from high to low temperatures for two tunnel coupling cases. The calculation assumes the symmetric coupling i.e., $\alpha = 1$. The calculation shows the typical change of $G(\varepsilon_d)$ from the Coulomb peaks to the Kondo plateau as the temperature decreases.

When the energy of the orbital ε_d decreases, the number of electrons in the quantum dot increases as $\langle n_d \rangle \sim 0 \rightarrow 1$ at $-\varepsilon_d \sim 0$ and $\langle n_d \rangle \sim 1 \rightarrow 2$ at $-\varepsilon_d \sim U$. At high temperatures $T \sim \Gamma$, there are two Coulomb peaks reflecting the change of $\langle n_d \rangle$.

The region $0 < -\varepsilon_d < U$, in which $\langle n_d \rangle \sim 1$, is the region where the Kondo effect takes place at low temperatures. As the temperature decreases, the height of the two peaks grows. At the same time, the peak positions shift to their center. When the temperature further decreases, the conductance at the central region gradually increases. Eventually, the two peaks merge into a single plateau. This plateau is the Kondo plateau. The change of $G(\varepsilon_d)$ from the Coulomb peaks to the Kondo plateau is observed in a wider temperature range for the weaker tunnel coupling case shown in Fig. 4A.

How do we understand the change of conductance: shift of the two peaks, and their merging into the single Kondo plateau when the temperature decreases? An important point in the quantum dot is that the Kondo temperature changes when the control parameter ε_d changes. That is, the Kondo temperature is a function of ε_d . The change of conductance can be naturally understood by exploring this point. In the region between the two Coulomb peaks where $\langle n_d \rangle \sim 1$, the analytical expression of the Kondo temperature is approximately given by

$$T_K = \left(\frac{U\Gamma}{2}\right)^{1/2} \exp\left(\frac{\pi\varepsilon_d(\varepsilon_d + U)}{2U\Gamma}\right). \quad (12)$$

For a fixed ε_d , the conductance as a function of the temperature, $G(T)$, largely increases logarithmically around the Kondo temperature $0.1 < T/T_K < 10$, and then reaches to its low temperature limit value given by Eq. (11). Eq. (12) shows that $T_K(\varepsilon_d)$ has a minimum value at the electron-hole symmetric point $-\varepsilon_d = U/2$, the center of the two Coulomb peaks. $T_K(\varepsilon_d)$ exponentially

Fig. 4 Calculated conductance as a function of ε_d , $G(\varepsilon_d)$, from high to low temperatures for (A) $\Gamma/\pi U = 1.0 \times 10^{-2}$ and (B) $\Gamma/\pi U = 3.0 \times 10^{-2}$. The number of electrons in the quantum dot is $\langle n_d \rangle \sim 1$ in $0 < -\varepsilon_d < U$ where the Kondo effect takes place. At high temperatures, two Coulomb peaks are observed at $-\varepsilon_d \sim 0$ and $-\varepsilon_d \sim U$ indicated by the vertical arrows. When the temperature decreases, the two peaks grow and shift to their center, and eventually merge into a single plateau, the Kondo plateau. The change of $G(\varepsilon_d)$ is observed in a wider temperature range for the weaker coupling case in (A). The numerical data for the figures are from (Izumida et al. (2001)). Modified from Izumida W, Sakai O, and Suzuki S (2001) Kondo effect in tunneling through a quantum dot. *Journal of the Physical Society of Japan* 70(4):1045–1053.

increases when ε_d deviates from this point. Note that Eq. (12) is meaningless outside the Coulomb peaks where $\langle n_d \rangle \sim 0$ and $\langle n_d \rangle \sim 2$ since it gives a much larger value than the temperature which characterizes the low temperature behavior of the conductance.

The conductance reaches its low temperature limit from the outer sides ($-\varepsilon_d \sim 0$ and $-\varepsilon_d \sim U$) to the center ($-\varepsilon_d = U/2$) when the temperature decreases. As a result, the growth of two peaks with a shift to their center and their merging into a single plateau are observed for decreasing temperatures.

The above discussed change of conductance is in fact, observed in a wider temperature region for the weaker tunnel coupling in Fig. 4A. This is because the difference of the Kondo temperature between the center and outer is larger for the weaker tunnel coupling.

From the above discussion it is clear that a fine tuning of the tunnel coupling is required to observe the well-separated Coulomb peaks to their growth to the Kondo plateau in a moderate temperature range for the experiments. The calculations explain the experimental observations. The details of this section has been reported earlier by Izumida et al. (2001).

Conclusion

In this chapter, the Kondo effect in a quantum dot was explained for the simplest case. The Kondo effect takes place in the electron transport through a quantum dot when the number of electrons in the quantum dot is odd. As the temperature decreases the conductance increases due to the resonant tunneling through the Kondo peaks emerging at the Fermi energy in the density of states in the quantum dot. Two Coulomb peaks gradually grow and shift to their center and they eventually merge into a single Kondo plateau at the lowest temperature. This change of the conductance is explained by the Kondo temperature, which is a function of the gate voltage. Controllable parameters, which are fixed in a related bulk system, provides a variety of the phenomena of the quantum dot.

In the following we briefly introduce some topics which were not elaborated in this chapter. For other topics, see also the chapter by Yamamoto (2023). These topics could include future direction of the research on the Kondo effects in the quantum dots.

The discussions in this chapter were restricted to the linear response conductance. Electron transport away from the linear response regime can be driven by the bias voltage. Measuring the electric current I by sweeping the bias voltage V_{bias} , dI/dV_{bias} is utilized as the measurement of the electron excitation spectra such as the local density of states. In addition, the Kondo effects in the nonequilibrium have been the important and fundamental subjects after the report by Meir et al. (1993). The nonequilibrium effects have been continuously studied and are up-to-date subjects, as can be found in the discussions on construction of effective low-energy Fermi-liquid theory (Oguri and Hewson, 2018; Filippone et al., 2018) and dynamics of splitting Kondo peak (Krivenko et al., 2019). Further, shot noise measurement provides more detail information on the nonequilibrium dynamics such as the effective charge of a charge carrier in the Kondo correlation, as can be found in the review by Kobayashi and Hashisaka (2021).

Non-degeneracy of the orbitals in the quantum dot was implicitly assumed in the explanation of this chapter. If the energy levels of the orbitals are well-separated, then an up-spin and a down-spin moment make a pair to form a spin-singlet state in each orbital.

Therefore, a local spin moment from an unpaired electron in the quantum dot appears only when the number of electrons in the quantum dot is odd. Many experiments support this simplified picture. However, this is not the case when there exists degeneracy of the orbitals as observed in the quantum dots having high symmetry such as vertical quantum dots (Kouwenhoven et al., 2001) and carbon nanotube quantum dots (Laird et al., 2015). Even when the number of electrons in the quantum dot is not only odd but also even, local spin moments in the quantum dot interact with the electrons in the leads then the Kondo effects take place. The multi-orbital effects have been discussed from the early stage as reported and reviewed with the NRG calculation (Izumida et al., 1998, Izumida and Sakai, 2005), and are still being investigated (Teratani et al., 2020).

Free design and control of the quantum system by using the quantum dots hybrid system enable us to investigate more details of the Kondo effects and related phenomena; such as using the double-quantum dot and quantum dots interferometers discussed from the early period of study of the Kondo effects in quantum dots as described in the review (Izumida and Sakai, 2005). Two-impurity Kondo effect, the effect of the competition between the Kondo effect and coupling of two local spin moments, has been studied with the double-quantum dot as discussed in a review (Chang and Chen, 2009). Interference and transmission phase shift related to the Kondo effects have been discussed with the quantum dots interferometers, as hybrid structures of Aharonov-Bohm circuits and quantum dots. They have been still the current topics as described in the literature (Eto and Sakano, 2020).

Exotic Kondo effects studied in bulk systems (Cox and Zawadowski, 1999) have motivated the studies, such as the non-Fermi liquid in the two-channel Kondo effect, with hybrid quantum dot systems as proposed by Oreg and Goldhaber-Gordon (2003). For more detail on this subject see the chapter by Yamamoto (2023).

Motivated by the intensive study on the realization of the Majorana quasi-particles in semiconductor nanowires with the superconducting correlations have triggered the study of the Kondo effect in quantum dots with the superconducting correlation, as can be found in the review by Aguado (2017).

These extensive studies of the Kondo effects in quantum dots are expected to reveal new aspects on the Kondo related physics.

Abstract

We discuss the experimental research on the Kondo effect using quantum dots. Kondo-correlated quantum dots have been used to demonstrate universal scaling, scattering phase shift, spatial extension, and non-equilibrium properties of tunable Kondo systems. Varieties of the Kondo effects in quantum dots, multi-channel Kondo effect, and coupling of the Kondo state to superconductors are also discussed.

Key points

- Kondo effect for localized spin 1/2 in a quantum dot
- universal scaling
- Kondo phase shift
- spatial extension of the Kondo cloud
- orbital and SU(4) Kondo effect
- charge Kondo effect
- non-equilibrium Kondo effect and scattering between quasi-particles
- multi-channel Kondo effect
- competition between Kondo singlet and Cooper-pair singlet

Introduction

The Kondo effect is known as the screening of localized spins by surrounding conducting electrons. The history of the Kondo effect dates back to 1930s when the development of cryogenic technologies started to allow researchers to measure the electrical resistance of varieties of materials at low temperatures. It was discovered by such experiments that the resistance of metals containing impurities increases at low temperature below around 10 K. It was identified later in 1950s that this happens when a metal is doped with magnetic impurities such as cobalt. It was unexpected because the resistance of a metal should decrease until finally saturates at low temperature owing to the reduction of electron scattering by phonon. This resistance upturn remained a mystery until Jun Kondo pointed out in 1964 that it occurs due to the interaction between the localized spins and the surrounding conducting electrons (Kondo, 1964). He considered the second-order scatterings, where the localized spin can flip through intermediate states that are allowed for a short period of time according to the quantum mechanics. The behavior of the localized spin surrounded by conducting electrons at the low temperature limit was not yet understood that time. This Kondo problem was then solved in the 1980s by the development of various theoretical tools, such as the scaling analysis and numerical renormalization group calculation. The associated ground state of the system known as the Kondo ground state is the many-body singlet state (Yosida, 1966). This state is the superposition of states, in which the localized spin and one of the conducting electrons form a spin-singlet state. The formation of such a many-body singlet state is interpreted as the screening of the localized spin by the conducting electrons.

The quantum dot (QD) offers ideal platforms to study the Kondo effect and demonstrate fundamental properties of the Kondo state (Glazman and Raikh, 1988, Izumida, 2023). The number of electrons in a QD is stabilized by its charging energy. When odd

number of electrons are confined in a QD, it contains an electron spin $1/2$, which serves as a localized spin. Its coupling to the reservoirs gives rise to the Kondo effect, as the reservoir electrons screen the localized spin in the QD. In the Kondo-correlated QD, the energy levels in the QD, the coupling strength to the reservoirs, and the charging energy are all tunable by means of the gate voltages, through which the Kondo temperature is controlled. The reservoirs attached to this many-body state are used to extract the Kondo physics by the electrical transport experiment. In addition, QDs in semiconductors can be combined with varieties of mesoscopic structures, such as quantum wires, quantum interferometers, and even superconductors.

Realization of the Kondo-correlated QD in the end 1990s triggered intense studies on the tunable Kondo systems using QDs (Goldhaber-Gordon et al., 1998a, Cronenwett et al., 1998). In contrast with bulk metals containing magnetic impurities, the electrical conductance through the QD in the Kondo regime, otherwise in the Coulomb blockade regime, increases at low temperature below the Kondo temperature T_K . This enhancement of the conductance at low temperature is one of the most representative signatures of the Kondo effect in QDs. Fundamental properties and physics of the Kondo-correlated QD have then been investigated. These include universal scaling of the conductance, Fermi liquid natures, the spatial extension, and non-equilibrium properties.

Overview

The Kondo state has several fundamental properties. One is the universal scaling characterized by the scaling energy T_K , which is also known as the Kondo temperature. The physical quantities such as the resistance through a Kondo state, magnetic susceptibility, and specific heat of a Kondo system are expressed as universal functions of T/T_K , where T is the temperature. The Kondo temperature T_K defines the strength of the spin-singlet coupling.

The second is the Fermi liquid nature. The zero-energy scattering through the Kondo state is described by scattering of a single quasi-particle. Since the localized spin is screened, the spin of the incident particle is not altered by the scattering at zero temperature. Instead, the fingerprint of the spin singlet screening appears as the $\pi/2$ phase shift of the scattered particle.

The third is the spatial extension. The many-body spin entanglement around the magnetic impurity is carried by conducting electrons travelling at the Fermi velocity v_F . The many-body spin coherence thus extends by v_F times the characteristic time scale $\hbar/(k_B T_K)$ of the Kondo spin screening dynamics, where $\hbar$ is Planck constant divided by 2π and k_B is the Boltzmann constant. Owing to this spatial extension, the Kondo state is also called “Kondo cloud”, as the cloud of conducting electrons that screens the localized spin. The spatial extension $\xi_K = \hbar v_F/(k_B T_K)$ can be much larger than the length scale of the Coulomb interaction, i.e., the classical charge screening length, as well as the associated length scale $\hbar v_F/J$ of the bare Kondo exchange coupling J . The Kondo cloud can thus mediate the spin entanglement between distant locations through the many-body coherence, between which the direct electronic interaction is negligible. The Kondo state is in this sense a large and fully quantum mechanical object.

We first discuss the above-mentioned fundamental properties demonstrated by the experiments using QDs. The universal scaling appears in the conductance through a Kondo-correlated QD obeying a universal function of T/T_K . Quantum interference experiments, where the Kondo-correlated QDs are embedded in electronic interferometers, are used to demonstrate the Kondo phase shift of $\pi/2$ and spatial extension of the Kondo cloud.

We then discuss various Kondo systems realized in QDs and the related physics. In QD systems, not only the spin $1/2$ of an electron confined in the QD but also other quantum numbers of the QD give rise to the Kondo effect. The exactly solvable Kondo system also serves as a platform to study the non-equilibrium physics. Non-equilibrium Kondo states where the scattering between quasi-particles plays a significant role is discussed. Quantum phase transition can also be studied using the Kondo-correlated QDs by the multi-channel Kondo effect in which multiple channels of the reservoirs contribute to the spin screening. Finally, we consider a QD coupled to superconducting leads and discuss the competition between the Kondo singlet and the Cooper-pair singlet.

Transport through a Kondo-correlated quantum dot and universal scaling

We consider a quantum dot (QD) with the charging energy U , which contains odd number of electrons and couples with two reservoirs by tunnel-coupling energies Γ_L and Γ_R . When the orbital degeneracy is lifted at zero magnetic field, the QD contains the spin $1/2$. In the Kondo physics, we consider all higher-order tunneling terms between the QD and the reservoirs. The higher-order tunneling results in the formation of the density of states around the Fermi energy of the reservoirs. This density of states is called the Kondo resonance. The width of the Kondo resonance defines the Kondo temperature and is determined by U , $\Gamma = \Gamma_L + \Gamma_R$, and the energy level ϵ_0 of the localized spin with respect to the Fermi energy:

$$k_B T_K = \frac{\sqrt{\Gamma U}}{2} \exp \left\{ \frac{\pi \epsilon_0 (\epsilon_0 + U)}{\Gamma U} \right\}. \quad (1)$$

Electrons can transport through this Kondo resonance for small bias between the two reservoirs at temperature lower than or comparable with T_K . When the localized spin is fully screened at the low temperature limit, the Kondo resonance is fully developed. In this “unitary limit,” the transmission through the QD is described by full transmission of a single channel. Note that only one transmitting channel of the reservoirs that couples most strongly to the QD can usually mediate the Kondo resonance. The conductance at zero temperature becomes

$$G_0 = \frac{2e^2}{h} \frac{4\Gamma_L\Gamma_R}{(\Gamma_L + \Gamma_R)^2} . \quad (2)$$

This conductance reaches the quantized conductance value $2e^2/h$ for $\Gamma_L = \Gamma_R$.

At finite temperatures, the conductance is suppressed from G_0 . In the strong-coupling regime defined as $T \ll T_K$, the conductance at temperature T becomes

$$G(T) = G_0 \left[1 - \left(\pi \frac{T}{T_K} \right)^2 \right] \quad (3)$$

This quadratic temperature dependence is characteristic of a Fermi liquid. The wide range of temperature dependence of the conductance is calculated using the numerical renormalization group method, from which the so-called empirical formula is derived as

$$G(T) = G_0 \left(\frac{T_K'^2}{T^2 + T_K'^2} \right)^s, \quad (4)$$

where $T_K' = \frac{T_K}{\sqrt{2^{1/s} - 1}}$, and $s = 0.22 \pm 0.01$ in the Kondo regime (Costi and Hewson, 1992). At high temperature $T \gg T_K$, the Kondo effect is suppressed. Eq. (4) indicates that $G(T)/G_0$ only depends on T/T_K , irrespective of the other parameters, U , Γ , and ϵ_0 .

Fig. 1 shows the experimental observation of the Kondo effect in the unitary limit (van der Wiel et al., 2000). In this experiment, the linear conductance through a Kondo correlated QD was measured as a function of the gate voltage V_{gl} that directly tunes the energy level ϵ_0 and slightly affects Γ with the temperature T as a parameter. The Kondo effect occurs at the conductance valleys called Kondo valleys around $V_{gl} = -413$ mV and -375 mV, where the conductance is suppressed at relatively high temperatures but reaches almost $2e^2/h$ at low temperature. This $2e^2/h$ conductance implies $\Gamma_L \sim \Gamma_R$ from Eq. (2) and that the Kondo resonance is almost fully developed at the lowest measurement temperature. The Kondo temperature is evaluated from the temperature dependence of the conductance using the empirical formula in Eq. (4) for each gate voltage V_{gl} . While $G(T)$ depends on V_{gl} , all data points collapse onto a single curve when the conductance is plotted as a function of T/T_K . This universal scaling of the conductance on T_K is one of the most remarkable properties of the Kondo-correlated QD.

When ϵ_0 becomes close to zero, or the localized level is close to the Fermi energy, i.e., near the Coulomb peaks, the number of the electrons in the QD fluctuates and the spin is not localized. Such a regime is known as the “mixed valence regime”. Although the conductance still increases with lowering the temperature in this regime, the temperature dependence becomes different from the one in the Kondo regime. In Eq. (4), s deviates from ~ 0.2 of the Kondo regime (Goldhaber-Gordon et al., 1998b).

The conductance through a Kondo-correlated QD also depends on the source-drain voltage V_{sd} (bias voltage between the two reservoirs) and the magnetic field B . Since the Kondo state is a quantum object of the energy scale $k_B T_K$, the large V_{sd} far exceeding $k_B T_K/e$ destroys the Kondo state. The differential conductance dI/dV_{sd} as a function of V_{sd} shows a peak at zero bias with the width of the order of $k_B T_K$. The magnetic field, on the other hand, lifts the degeneracy between the two spin states by the Zeeman energy. This also suppresses the Kondo effect. For dI/dV_{sd} as a function of V_{sd} , the zero bias peak is suppressed as B increases. At $g\mu_B B \sim 0.4k_B T_K$, the peak starts to split into two at $\pm g\mu_B B$ by twice Zeeman energy, where g is the g-factor and μ_B is the Bohr magneton (Oguri and Hewson, 2018). These peaks also disappear for $g\mu_B B \gg k_B T_K$.

Fig. 1 The Kondo effect in the unitary limit and universal scaling. (a) Conductance through a Kondo-correlated quantum dot (QD) measured as a plunger gate voltage that shifts energy levels of the QD with temperature as a parameter. Upper inset is the schematic of the Kondo-correlated QD. Lower inset is the temperature dependence at $V_{gl} = -413$ mV. (b) Temperature dependence of the conductance as a function of the temperature for different V_{gl} . Data is fitted to the empirical formula to extract the Kondo temperature. Inset is the same data plotted as a function of T/T_K . The figure is taken from ref. van der Wiel WG. et al. (2000) The Kondo effect in the unitary limit. *Science* 289: 2105–2108.

Phase shift through a spin 1/2 Kondo-correlated quantum dot

The phase shift of a single particle scattered off a QD is generally described by the Friedel sum rule, which is valid in the Fermi liquid or single-particle scattering regime:

$$\Delta\varphi = \pi N. \quad (5)$$

Here $\Delta\varphi$ is the phase shift of the particle and N is the number of electrons in the QD. When the energy levels in the QD are swept, the phase shift generally changes by π across a resonance through which one electron is added to the QD. At resonance, where electrons can transmit through the QD, $\Delta\varphi$ differs by $\pi/2$ from the one at off-resonance.

The Kondo ground state is known as a local Fermi liquid (Nozières, 1974), where the Friedel sum rule is applicable. Since this state is the many-body singlet state, both spin-up and spin-down states of the QD are occupied by half, i.e., $N = 1/2$. This leads to the $\pi/2$ phase shift through the Kondo-correlated QD according to Eq. (5). Since the $\pi/2$ phase shift occurs in a resonant scattering in general, there appears a resonance state aligned at the Fermi energy. The formation of the Kondo resonance is thus also understood as a consequence of the spin-singlet screening and the Friedel sum rule. On the same footing, observation of the $\pi/2$ phase shift is the direct evidence of the spin screening (Gerland et al., 2000). Indeed, there is one-to-one correspondence between the conductance and the phase shift at the low temperature limit.

This $\pi/2$ phase shift appears, for instance, in the context of "anti-Kondo effect" (Kang et al., 2001). The anti-Kondo effect occurs when a Kondo correlated QD is side-coupled to a quantum wire. An electron travelling through the quantum wire interferes between the path of direct transmission and the one that experiences a round trip through the Kondo-correlated QD. In the round trip through the QD, the electron acquires the phase shift of 2 times $\pi/2$. The resulting π phase shift leads to the destructive interference with the direct path. The conductance through the quantum wire is thus suppressed in the Kondo regime. Sato et al. demonstrated this Anti-Kondo effect in such a system and showed that the result is consistent with the Kondo $\pi/2$ phase shift (Sato et al., 2005). They revealed the "Fano-Kondo" effect, where a continuous mode of the quantum wire interferes with the discrete Kondo level.

The more direct and precise measurement of the Kondo phase shift was realized by embedding a Kondo-correlated QD in one of the paths of an electronic two-path interferometer (Takada et al., 2014). The setup demonstrated in ref. (Takada et al., 2014) allows for measurement of the phase shift with precision much higher than 0.1π . In the interferometer shown in Fig. 2A, the relative phase

Fig. 2 Measurement of the Kondo phase shift as the proof of spin screening. (A) The quantum interferometer device used to measure the Kondo phase shift. The interferometer works as an electronic Mach-Zehnder interferometer when the tunnel-coupled wires are tuned to act as beam splitters. The Kondo-correlated quantum dot is embedded in one of the arms of the Aharonov-Bohm (AB) ring. (B) Observed AB oscillation with V_p as a parameter at $T \sim 40$ mK (upper panel: oscillating component of the current I_2) and extracted phase shift across the QD plotted with the average current I_2 (lower panel). The phase plateau at $\pi/2$ appears in the Kondo valley around $V_p \approx -0.09$ V. $T_K \sim 50$ mK in the middle of the Kondo valley. Data is identical with the one presented in ref. Takada S et al. (2014) Transmission phase in the Kondo regime revealed in a two-path interferometer. *Physical Review Letters* 113: 126601.

between the two paths can be modulated by the perpendicular magnetic field via the Aharonov-Bohm (AB) phase. The transmission phase through the Kondo-correlated QD is measured as the phase of the AB oscillation. In Fig. 2B, the Kondo $\pi/2$ phase shift appears as a plateau in the Kondo valley for $T < T_K$. The comparison of this experimental observation with numerical renormalization group calculations also allowed for precise evaluation of the Kondo temperature.

In the mixed valence regime, where ϵ_0 becomes away from the middle of the Kondo valley and Γ/U is too large, the phase shift deviates from $\pi/2$. This is because the density of states that originates from the higher order tunneling no longer aligns with the Fermi energy and becomes away from the resonance. This phase shift in the mixed valence regime has also been experimentally confirmed (Takada et al., 2016).

Spatial extension of the Kondo cloud

The spatial extension $\xi_K = \hbar v_F / (k_B T_K)$ of the Kondo cloud is one of the most important properties of the Kondo state (Affleck, 2010). As mentioned above, the many-body spin coherence carried by the conducting electrons extends by $\xi_K = v_F / (k_B T_K)$ beyond the direct electronic and magnetic coupling distance. This cloud mediates the quantum mechanical coupling between distant spins to entangle them and plays an important role in variety of strongly correlated systems.

This spatial extension had attracted considerable attention since the infancy of the Kondo physics and numerous experiments have been attempted to detect it. Difficulty in detecting the Kondo cloud stems from the short time scale $\tau_K = \hbar / (k_B T_K)$ of the typical Kondo dynamics, $\tau_K \sim 60$ ps for $T_K = 100$ mK. One would need to measure the spin correlation between different positions within τ_K before the spins rotate, if one directly tries to detect the Kondo cloud via the spin correlation. This is a challenging task for the present technology. Alternative ways to detect the Kondo cloud have been proposed theoretically using QDs with finite size reservoirs of length L . Since ξ_K is the only length scale associated with the Kondo effect, certain physical quantity should be a universal function of L/ξ_K , similarly with the conductance being a universal function of T/T_K . In these schemes, because the energy spacing of a finite size one-dimensional reservoir of length L is $\delta\epsilon \sim \pi \hbar v_F / L$ and $\xi_K = \hbar v_F / (k_B T_K)$, L/ξ_K can be replaced with $k_B T_K / \delta\epsilon$. Therefore, one might argue that these schemes do not detect the length scale but merely compare the energy scales $k_B T_K$ and $\delta\epsilon$. However, as clearly stated in ref. 11, this conversion between the length scale and the energy scale is the essence of the coherent extension of the Kondo cloud. This conversion is possible only when the spin singlet coherence is extended over the length scale of ξ_K , which justifies the Kondo cloud detection by the L/ξ_K scaling.

Experimental observation of the Kondo cloud was realized recently in this strategy, employing a Kondo-correlated QD coupling on one side to a Fabry-Perot (FP) interferometer of variable length L , which further couples to a macroscopic reservoir (Borzenets et al., 2020). In the device shown in Fig. 3A, the QD is tuned to be more strongly coupled to the right one-dimensional reservoir that houses the FP interferometer to form a Kondo cloud there. In this setup, T_K is affected by the FP interference through modulation of the density of states of the reservoir if the Kondo cloud extends to the end of the FP interferometer. This results in oscillation of the Kondo temperature when the gate voltage V_{QPC} of one of the quantum point contacts (QPCs) is swept to change the FP interferometer length L by the order of Fermi wavelength. Using the maximum $T_{K,max}$ and minimum $T_{K,min}$ of the Kondo temperature oscillation, the modulation of the Kondo temperature is quantified by $T_{K,max}/T_{K,min}$, while the bare Kondo temperature and bare Kondo screening length without the interferometer are $T_{K,\infty} \approx (T_{K,max}/T_{K,min})^{0.5}$ and $\xi_{K,\infty} = \hbar v_F / (k_B T_{K,\infty})$, respectively. Defining the parameter $0 \leq \eta \leq 1$ of the density of states modulation, $T_{K,max}/T_{K,min}$ becomes a universal function of η and $L/\xi_{K,\infty}$, irrespective of other parameters. For small perturbation $\eta \ll 1$,

$$\ln(T_{K,max}/T_{K,\infty})/\eta = -\ln(L/\xi_{K,\infty}) \quad (6)$$

is simply a function of $L/\xi_{K,\infty}$. This function can be interpreted as the universal shape of the Kondo cloud.

Fig. 3B shows the universal shape of the Kondo cloud obtained in the experiment. While the FP interference was activated by three QPCs with different L , all data points collapse on a single curve, irrespective of the other parameters such as Γ , ϵ_0 , and $T_{K,\infty}$. This result shows that the cloud mostly lies within ξ_K and accompanies a long tail beyond ξ_K . The absolute value of the spatial extension $\xi_K = \hbar v_F / (k_B T_K)$ was also confirmed, which is the order of several micrometers. On the other hand, the charge screening length that is comparable with the distance from the surface gate to the one-dimensional channel is the order of 200-300 nm. It confirms that the spatial extension of the spin entanglement is much larger than the length of the direct electronic or magnetic exchange interaction. This result also confirms indirectly that the time scale of the Kondo dynamics is $\tau_K = \xi_K / v_F = \hbar / (k_B T_K)$.

Varieties of the Kondo effect in quantum dots

We have discussed the standard Kondo effect occurring for a localized spin $1/2$ in a QD screened by conducting electrons of reservoirs. However, the Kondo effect does not only occur for a localized spin $1/2$ but also for other degenerate states. QDs serve as platforms to study varieties of the tunable Kondo effect, which are often not accessible in other systems. In this section, we describe some of the varieties, although we do not attempt to discuss all of them here.

As the first example, suppose there are two electrons confined in a QD. In the presence of a high perpendicular magnetic field B , spin triplet $S = 1$ state with 3-fold degeneracy becomes the ground state owing to the exchange interaction. Strictly saying,

Fig. 3 Observation of the Kondo cloud. (A) Schematic of the device used for observation of the Kondo cloud. (B) Real shape of the Kondo cloud. Modulation of the Kondo temperature by V_{QPC} for the density of states modulation of $\sim 10\%$ is plotted as a function of $L/\xi_{K,\infty}$. The data deviate from the analytical formula of Eq. (6) (grey dashed curve) for large $L/\xi_{K,\infty}$. In this experiment, T_K was evaluated from the temperature dependence of the conductance and using the empirical formula (Eq. 4). This empirical formula is valid for the constant density of states of the reservoirs. For large $L/\xi_{K,\infty}$, the modulation of the density of states induced by the FP interference is not negligible in the energy scale of $k_B T_K$, leading to the deviation of obtained T_K from the one calculated for the constant density of states. However, numerical renormalization group calculation of the temperature dependence of the conductance and its fit to the empirical formula (red crosses) reproduce the experimental observation. Figure is taken from ref. Borzenets IV et al. (2020) Observation of the Kondo screening cloud. *Nature* 579: 210–213.

degeneracy of the $S = 1$ states is lifted by the Zeeman energy, however, they can be regarded as in degeneracy if the Zeeman splitting is smaller than the other energy scales of the system. This degenerate $S = 1$ state and coupling to the reservoirs also give rise to the Kondo effect. As mentioned, the Kondo state is usually mediated by a single channel of the reservoirs. If it is also the case, the single channel ($S = 1/2$) is not enough to fully screen $S = 1$ consisting of two electrons. This situation is called “under screening”. However, the $S = 1$ state in the QD involves two orbitals owing to the antisymmetric two-body orbital wave function for the exchange of the two particles, through which two channels in the reservoirs can contribute to the spin screening. Therefore, we expect full screening of the localized $S = 1$ at zero temperature. On the other hand, the Hund’s coupling suppresses the Kondo temperature. it has not been possible to observe it in QD systems owing to the small T_K .

The situation becomes different at certain B , where the spin singlet $S = 0$ and triplet $S = 1$ states become degenerate. Because $S = 0$ state can couple to all three $S = 1$ states via cotunneling (higher order tunnel coupling to the reservoirs) through vertical states, the spin screening is further promoted. The Kondo temperature T_K is enhanced and becomes even larger than that of the $S = 1/2$ Kondo effect. Fig. 4 shows the observation of the Kondo effect at the singlet-triplet degeneracy demonstrated using a rectangular vertical QD (Sasaki et al., 2000). The Kondo effect arises for $N = 6$ exactly at the transition between the spin singlet and triplet state. At the transition ($B = 0.22$ T), the Zeeman energy is much smaller than the Kondo temperature and thus the strong Kondo effect is observed in the transport experiment as enhancement of the linear conductance at low temperatures.

There are also other types of the “orbital” Kondo effect, which occurs when there are degenerate orbitals in a QD. The orbital degree of freedom or the orbital polarization can be screened by the reservoir electrons at low temperature. The orbital Kondo effect was also observed for a carbon nanotube QD that has the degenerate clockwise $|+\rangle$ and anti-clockwise $|-\rangle$ orbitals originating from the K and K’ valley of graphene (Jarillo-Herrero et al., 2005). When the magnetic field B is applied to the direction parallel to the nanotube, energy levels of the QD shift toward opposite directions between $|+\rangle$ or $|-\rangle$. At a certain B , while the spin degeneracy is lifted by the Zeeman energy, two different orbital states of the same spin, one from $|+\rangle$ and the other from $|-\rangle$, become degenerate. The purely orbital Kondo effect occurs around this degeneracy point. At $B = 0$, there is 4-fold degeneracy originating from the spin and orbital. The Kondo effect for the SU(4) symmetry (SU(4) Kondo effect) was also demonstrated (see the following section and Fig. 5).

Fig. 4 The $S = 1$ Kondo effect. (A) and (B) schematic and scanning electron microscopy (SEM) image of the rectangle vertical quantum dot. (C) Schematic energy diagram of the electron state as a function of the magnetic field. (D) Observation of the $S = 1$ Kondo effect. It appears for $N = 6$ at $B = 0.22$ T as enhancement of the zero bias linear conductance (color scale) in the Coulomb blockade regime. Figure is taken from ref. Sasaki S et al. (2000) Kondo effect in an integer-spin quantum dot. *Nature* 405: 764–767 (Fig. 2).

(A) SU(4) Kondo effect observed at $B = 0$ and SU(2) Kondo effect observed at $B = 10$ T. The conductance through the SU(4) Kondo state is twice as large as the one through the SU(2) Kondo state. (B) Enhanced current noise as a function of the backscattered current. The effective charge of the system is evaluated from the slope. Figure is taken from ref. Ferrier M et al. (2017) Quantum fluctuations along symmetry crossover in a Kondo-correlated quantum dot. *Physical Review Letters* 118: 196803.

The orbital effect and SU(4) Kondo effect were also demonstrated for a double quantum dot (DQD) (Keller et al., 2014). In a DQD, the pseudospin defined by the presence of the electron in either of the QDs plays a role of the orbital.

Finally, we briefly discuss the “charge” Kondo effect. The charge Kondo effect was proposed by Matveev (Matveev, 1991) before the standard spin $1/2$ Kondo effect was realized for a QD. Consider a relatively large and high-density metallic island (QD), whose

orbital energy spacing is much smaller than $k_B T$ but whose charging energy U is larger than $k_B T$. Suppose also that the spin degree of freedom is absent owing to the application of a high magnetic field. In such a classical degenerate regime, spin and orbital degrees of freedom do not play a role. The only remaining degree of freedom is the charge, defined by the number N of electrons in the island. The charge Kondo effect is expected when the charge N state and $N + 1$ state of the electronic system are degenerate at the resonance of the $(N + 1)$ th state of the island aligned with the chemical potential of the reservoir. The electron spin of the standard Kondo effect is replaced with the location of the $(N + 1)$ th electron inside ($|\uparrow\rangle$) or outside ($|\downarrow\rangle$) the island. The misalignment from the degenerate point plays the role of the applied magnetic field. This charge Kondo effect is realized using a metallic island and reservoirs of the spin-polarized quantum Hall edge channels (see Fig. 6A) (Iftikhar et al., 2015). Although the Kondo temperature T_K is relatively low owing to small U , it is easy to control the coupling to the reservoir channels. The charge Kondo system is useful to study multi-channel Kondo effect, where the localized spin is screened by multiple channels. The multi-channel Kondo effect will be discussed in the later section.

Fig. 6 Charge Kondo effect and renormalization flow of two- and three-channel Kondo effect. (A) SEM image of the device and schematic description of the measurement. Inset is the schematic for the two-channel Kondo experiment. (B) Renormalization flow of the two-channel Kondo effect. Arrows indicate change of the conductance for lowering the temperature. (C) Renormalization flow of the three-channel Kondo effect. The transmission probabilities of QPC1 and QPC3 are identical: $G_1 = G_3$. $G_{1,3} = (G_1 + G_3)/2$ and G_2 were measured while lowering the temperature. For $G_1 = G_2 = G_3$, the system approaches to the three-channel Kondo fixed point (green), otherwise, it approaches to the single channel or two-channel fixed point. Origin of the super-ballistic conductance exceeding e^2/h has not yet been understood. Figures are taken from refs. Iftikhar Z. et al. (2015) Two-channel Kondo effect and renormalization flow with macroscopic quantum charge states. *Nature* 526: 233–236 and Iftikhar Z et al. (2018) Tunable quantum criticality and super-ballistic transport in a “charge” Kondo circuit. *Science* 360: 1315–1320.

Non-equilibrium Kondo effect and two-particle scattering

The Kondo ground state is known as the local Fermi liquid, where zero-energy transport is described in a single quasi-particle picture. When a source-drain bias $V < k_B T_K/e$ is applied to the Kondo-correlated quantum dot, the system is brought into the non-equilibrium Kondo state, where the scattering between quasi-particles also plays a significant role. The two-particle scattering results in enhancement of the effective charge e^* from the electron charge e . $e^*/e = 5/3$ was predicted for the ideal SU(2) (screening of the spin 1/2) Kondo effect (Sela et al., 2006), and $e^*/e = 3/2$ was predicted for the SU(4) Kondo effect at half filling ($N = 2$). More generally, e^* for the SU(N) Kondo effect at half filling is determined by a single parameter R known as Wilson ratio (Sakano et al., 2011, Mora et al., 2009):

$$e^* = \frac{1 + 9(N-1)(R-1)^2}{1 + 5(N-1)(R-1)^2}. \quad (7)$$

R characterizes the strength of the spin fluctuation and approaches to $N/(N-1)$ for the ideal Kondo regime. $(R-1)^2$ is determined by the ratio of the “renormalized” U and Γ by the Kondo effect.

The measurement of the current shot noise has widely been used to evaluate the effective charge e^* of electronic systems. For the Kondo-correlated QD, influence of the two-particle scattering appears as enhancement of the current noise from the one expected for the single-particle scattering. e^* is obtained from the backscattered current I_K and resulting increase of the current noise power spectrum density S_K as $2e^* = S_K/I_K$. Here, I_K is experimentally obtained as the nonlinear part of the current $I_K = I_{sd} - GV_{sd}$, where G is the linear conductance and I_{sd} is the measured total current. S_K is obtained from the measured power spectrum density S and subtracting the single-particle partition noise calculated from the transmission probability of the channel.

Fig. 5 shows the experiment on current noise through a Kondo-correlated QD (Ferrier et al., 2017). A carbon nanotube QD was employed in the experiment. Large U of the QD and resulting large T_K allows for precise evaluation of the effective charge e^* at the low temperature limit. When two electrons are confined in the shell of 4-fold spin and orbital degenerate states, it is possible to tune the system between the fully screened SU(4) Kondo regime and the SU(2) Kondo regime by adjusting the magnetic field direction such that orbital energy spacing between $|+\rangle$ or $|-\rangle$ induced by the magnetic field B coincides with the spin Zeeman energy. At $B = 0$, SU(4) Kondo effect occurs owing to 6-fold degeneracy, out of which two states have zero magnetic moment. In the presence of B , the 6-fold degeneracy is lifted, but the spin-polarized and orbital-polarized states still have the same energy, giving rise to the SU(2) Kondo effect. The system therefore undergoes crossover from SU(4) to SU(2) Kondo state by the magnetic field (see Fig. 5A). As seen in Fig. 5B, the theoretically predicted effective charge e^* for the SU(2) and SU(4) Kondo effect was confirmed experimentally.

In the series of experiments, it was confirmed that up to two-particle scattering is usually enough to describe the non-equilibrium transport through the Kondo-correlated QD. However, in the presence of the magnetic field, the three-particle interaction needs to be considered (Hata et al., 2021). Suppression of the dI/dV_{sd} peak around zero bias and its splitting for $g\mu_B B > \sim 0.4k_B T_K$ observed in experiments are theoretically reproduced by considering the three-particle interaction.

Multi-channel Kondo effect

The Kondo-correlated QDs also serve as platforms to investigate quantum phase transitions because the Kondo physics based on the Anderson impurity model provides solvable problems. In a standard Kondo-correlated QD, only a single channel of the reservoir that most strongly couples to the QD mediates the Kondo state. In certain geometries, however, it is possible to tune the coupling strengths of two or more channels to the QD and make them identical. When two channels of the reservoir are equally coupled to a QD and contribute to the screening of the localized spin, the two-channel Kondo effect occurs (Nozières and Blandin, 1980). In contrast with the standard Kondo state of a single channel, the two-channel Kondo state is known to be a non-Fermi liquid. It locates at the quantum critical point of a parameter space at the border between the two single-channel Kondo states screened by different channels.

In the single-channel Kondo effect, the localized spin $S = 1/2$ is fully screened by the reservoir spin $s = 1/2$ at zero temperature (full screening). In the two-channel Kondo effect, on the other hand, the localized spin is “over-screened”. The two reservoir spins $s = 2 \times 1/2 = 1$ from the two channels that screen the localized spin leaves residual spin $1 - 1/2 = 1/2$, which is further screened by the reservoir electrons. Therefore, the low-energy excitation is no longer a single quasi-particle excitation but collective excitation. Instead of the Fermi liquid’s T^2 dependence of the conductance near zero temperature, $T^{0.5}$ dependence is theoretically expected. In more general, when $N(>1)$ channels are equally coupled to the localized spin 1/2, there is a residual entropy of $k_B \ln(2\cos[\frac{\pi}{N+2}])$, which leads to the power law dependence with non-Fermi liquid scaling exponent.

The two-channel Kondo effect was demonstrated using a QD with a localized spin 1/2 connected to three reservoirs (Potok et al., 2007, Keller et al., 2015). One of the reservoirs consists of a large QD directly coupled to the Kondo-correlated QD. The orbital energy spacing of the large QD is smaller than $k_B T$ but its charging energy is larger than $k_B T$. This charging energy isolates the channel through this large QD from those of the other two reservoirs without being affected by the orbital state of the large QD. By tuning

the exchange coupling J_1 between the Kondo-correlated QD and the large QD, and J_2 between the Kondo-correlated QD and the other infinite reservoirs, the system can be tuned into the two-channel Kondo regime. The two-channel Kondo regime appears in the vicinity of the quantum critical point $J_1 = J_2$ between the two single-channel Kondo states - one formed in the infinite reservoirs and the other formed in the other reservoir through the large QD. In the experiment, the temperature and source-drain voltage dependence of the conductance of the Kondo-correlated QD through the two reservoirs without the large QD is consistent with theoretical calculation for the two-channel Kondo effect. Under the application of source-drain voltage the deviation of the linear conductance from the zero-bias conductance showed $V_{sd}, \sqrt{V_{sd}}$ dependence for $k_B T \ll eV_{sd}$ as expected for the two-channel Kondo effect.

The two-channel Kondo effect was also observed in a charge Kondo system (see Fig. 6) (Ifrikhar et al., 2015). By tuning the transmission probability of two quantum point contacts (QPCs), one can tune the system into the two-channel Kondo regime at the quantum criticality. Because the transmission probability τ and charge-pseudospin coupling J has one-to-one correspondence, it is straightforward to achieve $J_1 = J_2$. Experiment in ref. (Ifrikhar et al., 2015) revealed “renormalization flow” by measuring the linear conductance G_1 and G_2 of the two QPCs as a function of the temperature (Fig. 6B). Here, G_1 and G_2 are obtained from the conductance matrix of the system. When the temperature is lowered, the system approaches to the single-channel Kondo regime $G_1 \ll G_2 \sim e^2/h$ or $G_2 \ll G_1 \sim e^2/h$ except for $J_1 = J_2$. At $J_1 = J_2$, both G_1 and G_2 approaches to e^2/h at low temperature obeying the universal function of T/T_K . Here, T_K is determined numerically as a function of the charging energy U of the metallic island and the transmission probability τ of the two QPCs. In this charge two-channel Kondo effect, the conductance of the system through the two QPCs as well as G_1 and G_2 decays linearly with T at low temperature $T \ll T_K$ instead of T^2 . This T -linear dependence is unique for the “charge” two-channel Kondo system that has a small bandwidth (Mitchell et al., 2016).

In the charge Kondo system, three-channel Kondo effect was also demonstrated by tuning the three QPCs such that all of them have the same transmission probability (Ifrikhar et al., 2018). The linear conductance G_1 , G_2 , and G_3 of the three QPCs were measured as functions of the temperature. The three-channel Kondo conductance $G_{1,2,3} = (G_1 + G_2 + G_3)/3$ at zero temperature is no longer e^2/h . $G_{1,2,3}$ approaches to $G_{3CK} = 2\sin^2(\pi/5)e^2/h \sim 0.7e^2/h$ at low temperature (see Fig. 6C). $|G_{1,2,3} - G_{3CK}|$ is found to be proportional to $T^{2/5}$, revealing the non-Fermi liquid scaling exponent of the three-channel charge Kondo effect.

Kondo effect with superconductivity

One of the advantages of the Kondo-correlated QD is that the Kondo state can be made coupled with various types of reservoirs such as ferromagnets, superconductors, and even topological insulators. As a typical example, we briefly discuss the experiments on Kondo-correlated QDs coupled to s-wave superconducting leads.

Consider a QD containing spin 1/2 coupled with superconducting leads. There are two competing spin-singlet couplings in the system. One is the Kondo coupling with energy $k_B T_K$, and the other is the Cooper pair coupling with the superconducting gap energy Δ . For $k_B T_K \gg \Delta$, the Kondo coupling is dominant and the localized spin in the QD is screened by forming a sub-gap spin singlet state. For $k_B T_K \ll \Delta$, the Kondo effect is suppressed owing to the absence of states in the superconducting gap, leaving the localized spin as a doublet state. The antiferromagnetic coupling between this spin and superconducting quasiparticles leads to formation of the Yu-Shiba-Rusinov (YSR) state. At $\Delta/(k_B T_K) \sim 1.1$, the first order quantum phase transition between these two states occurs.

The Kondo-correlated QD coupled with superconducting leads has been realized using carbon nanotube QDs, self-assembled InAs QDs, and InAs nanowire QDs, by depositing two superconducting leads (Buitelaar et al., 2002; Eichler et al., 2007; Buizert et al., 2007; Eichler et al., 2009; Kanai et al., 2010). In these Kondo-superconducting QD systems, both T_K and Δ can be tuned by means of the gate voltages and magnetic field. Zero bias linear conductance across the superconducting junction reflects the strength of the Kondo effect or the formation of the sub-gap Kondo resonance. It is suppressed for $k_B T_K < \Delta$ even at low temperature $T < T_K$, while it recovers for $k_B T_K > \Delta$. At low enough temperature, the zero bias conductance normalized by its value for normal metal leads becomes a function of $\Delta/(k_B T_K)$ (Buizert et al., 2007).

It is worth noting that the Kondo effect does not only compete with the superconductivity but can also enhance superconductivity. Counter-intuitively, the supercurrent through the QD junction is significantly enhanced for $k_B T_K > \Delta$. This is because the magnetic doublet of the QD that suppresses the supercurrent by forming a π Josephson junction is screened by the Kondo effect. This enhancement of the supercurrent by the Kondo effect has also been experimentally observed (Eichler et al., 2009; Kanai et al., 2010).

Conclusion

Quantum dots serve as platforms to study tunable Kondo effects. Fundamental properties of the Kondo effect such as the universal scaling, phase shift, spatial extension, and non-equilibrium properties have largely been revealed by experiments. Varieties of the Kondo effects, which are not easily accessible in other systems, have also been observed in QD systems.

While the multi-channel Kondo effect and competition with the Cooper-pair coupling have been investigated, phase transitions of systems consisting of Kondo states have not yet been fully understood. These include systems containing multiple magnetic

impurities or multiple QDs. It is also important to understand and control dynamics of the Kondo effect. Although observation of the spatial extension $\xi_K = \hbar v_F / (k_B T_K)$ of the Kondo cloud suggests its time scale $\tau_K = \xi_K / v_F = \hbar / (k_B T_K)$, how the Kondo cloud attains its equilibrium state by certain coupling to environment has not yet been revealed.

In-situ control of quantum phase transitions and many-body dynamics of the Kondo systems using QDs may also stimulate further research toward development of novel quantum devices. For example, if one can reveal and control phase transitions and dynamics of Kondo lattice systems, it may become possible to entangle and control distant localized spins via Ruderman–Kittel–Kasuya–Yosida (RKKY) interaction mediated by overlapping Kondo clouds. The multi-channel Kondo systems also involve free Majorana fermions and parafermions, which may be used for topological quantum computation.

Further experiments using Kondo-correlated QDs may address these issues in the future.

Abstract

The textures of the spin fields in geometrically confined systems such as, quantum dots and quantum rings are introduced in this chapter. Analogous to the topological soliton skyrmion, the topological charge of the spin fields in real space are given by the winding numbers and Pontryagin indices. The trivial and non-trivial patterns of the spin fields are discussed. Spin-orbit couplings, inhomogeneous magnetic fields, and density-related effects, such as Coulomb interaction and impurity, make the spin textures vary in style and topologically non-trivial. Different topological charges can be considered to represent information in real devices, thus the manipulation of the topological charge in the quantum dots and rings by external conditions may be useful in spintronics and information techniques.

Key points

- Spin fields are textured topologically in quantum dots and quantum rings when the spin-orbit couplings are present. The topological charge is defined by the winding number.
- Rashba and Dresselhaus spin-orbit couplings induce spin textures with topological charge +1 and -1, respectively, in quantum dots and rings.
- Inhomogeneous magnetic fields texture the spin field with different topological charges higher than ± 1 and are possible to form skyrmions in quantum dots.
- Coulomb interaction significantly changes the topological charge of the spin textures by deforming the density of electrons.
- The topological charge varies periodically in a quantum ring when both the Rashba and Dresselhaus spin-orbit couplings are present. The period is slightly deviated from the Aharonov-Bohm period by the width of the ring.
- A non-magnetic impurity in a quantum ring is able to promote the topological charge of the spin field to ± 2 .

Introduction

Topological spin textures have been extensively studied in many systems in condensed matter physics. Basically, the spin fields of electrons are textured by external magnets, spin-orbit coupling (SOC) or the electrons correlations. When the external magnetic field has a non-trivial pattern, the spin field then simply follows the magnetic field and is textured in accordance with the relations provided by the semiclassical Landau-Lifshitz-Gilbert equation. The Dzyaloshinskii-Moriya interaction microscopically induced by the SOC gives rise to spin skyrmions in helical magnets (Mühlbauer et al., 2009; Yu et al., 2010; Nagaosa and Tokura, 2013) and pseudospin skyrmions in a graphene bilayer (Côté et al., 2010, 2011). Synthetic SOC's can also be manufactured in the cold atomic

[☆]Change History: August 2022. Authors W Luo, S Peng, and T Chakraborty are involved in preparing the update.

gases to texture the spin in a skyrmion-like pattern (Hu et al., 2012; Wilson et al., 2013). In the quantum Hall regime, the single-particle excitations governed by the nonlinear σ models carry topological non-trivial spin textures and the spontaneous symmetry breaking state emerged as the skyrmion or meron crystals (Ezawa, 2000).

In this chapter, we focus on the textured spin fields and their topology in confined nanostructures, e.g., quantum dots (Maksym and Chakraborty, 1990; Chakraborty, 1999; Bimberg et al., 1999; Kouwenhoven et al., 2001; Hanson et al., 2007; Kloeffer and Loss, 2013) and quantum rings (Chakraborty and Pietiläinen, 1995a; Hong-Yi Chen, 2008; Chakraborty et al., 2017, 2018; Wendler and Fomin, 1995; Lucignano et al., 2007). The topological electron states in real space induced by various effects could be important for spintronics and quantum information applications (Žutić et al., 2004; Šmejkal et al., 2018; Gomonay et al., 2017).

If there is no spin-orbit coupling, then the spin is a good quantum number. Each state of the quantum dot or quantum ring can be labeled by the spin quantum number which for simplicity is represented by the eigenvalue of the Pauli matrix σ_z . Thus, for a single-electron state, its spin field is simply polarized along the $\pm z$ axis, and the spin texture is trivial. In a many-electron case, the Coulomb interaction also commutes with σ_z and does not directly and explicitly change the spin textures. Here we restrict ourselves on the single-electron and the two-electron cases for simplicity.

To find non-trivial spin textures in a quantum dot/ring, either inhomogeneous magnetic fields or a spin-orbit coupling (Manchon et al., 2015; Ren et al., 2016) is necessary. The term of SOC (for instance Rashba SOC) in the Hamiltonian can be written as a momentum-dependent gauge. Thus the effect of the SOC can be treated as an effective momentum-dependent magnetic field. Naively, in the momentum space, the spin may be textured to a vortex-like pattern by aligning with this effective magnetic field, which in fact depends on the form of the SOC. However, if there is no confinement or magnetic field in real space, the spin texture would disappear or be as trivial as the polarized spin field. Since the Hamiltonian commutes with the momentum operator and the translational operator, $[\mathcal{H}, p_{x,y}] = 0$, the wave function must contain the plane wave part $e^{-ik \cdot r}$, where k is the wave vector, and the spin texture at the single electron level needs to obey the translational symmetry in real space.

Once the space is confined, say in a quantum dot/ring, $[\mathcal{H}, p_{x,y}] \neq 0$, the translational symmetry is naturally broken. The spin textures in the momentum space can be recovered in real space. The spin textures in quantum dot hydrogen (a single electron in a QD), quantum dot helium (two electrons in a QD) and the single-electron quantum ring (with and without an impurity) in the presence of magnetic fields will be discussed. For simplicity, only the Rashba and linear Dresselhaus SOC (Roland, 2003) are considered. Considering that the quantum dot/ring systems can be conveniently tuned by gates, the tuning of the topological features by varying the SOC and the external fields in these systems are also discussed.

Models

The quantum dots and quantum rings have been extensively studied both theoretically and experimentally for decades. Here we do not constrain ourselves with a specific set-up or material. The general models will be presented here that would be suitable for different materials.

The Hamiltonian is given by four parts $\mathcal{H} = \mathcal{H}_0 + \mathcal{V} + \mathcal{H}_{\text{SOC}} + \mathcal{H}_C$, where $\mathcal{H}_0$ describes the free electron, $\mathcal{V}$ is the confinement potential, $\mathcal{H}_{\text{SOC}}$ contains the SOC terms, and $\mathcal{H}_C$ represents the Coulomb interaction. The confinement potential is different in QD and QR: $\mathcal{V}_{\text{QD}} = \frac{m^*}{2} (\omega_x^2 x^2 + \omega_y^2 y^2)$ and $\mathcal{V}_{\text{QR}} = \frac{m^*}{2} \omega^2 (r - R)^2$, where m^* is the effective mass of the electron. The QD could be anisotropic: the confinement frequencies $\omega_{x,y}$ in different directions are independent, while the QR is supposed to be a regular circle with radius R for simplicity. Other terms in the single-particle Hamiltonian read

$$\mathcal{H}_0 = \frac{\mathbf{p}^2}{2m^*} + \frac{\Delta}{2} \sigma_z, \quad (1)$$

$$\mathcal{H}_{\text{SOC}} = g_1 (\sigma_x P_y - \sigma_y P_x) + g_2 (\sigma_y P_y - \sigma_x P_x), \quad (2)$$

where $\mathbf{P} = \mathbf{p} - e\mathbf{A}$ is the kinetic momentum with the vector potential $\mathbf{A}$, $\sigma_{x,y,z}$ are Pauli matrices, Δ is the Zeeman energy, and $g_{1,2}$ are the Rashba and Dresselhaus SOC strengths, respectively.

The Hamiltonian in some special cases can be solved exactly, such that the single-electron case with $g_1 = \pm g_2$ can be converted to a quantum Rabi model (Luo et al., 2019). However, the general form of the Hamiltonian may not be exactly solvable, especially when the Coulomb interaction is present. A reliable way to solve the Hamiltonian is to use the numerical exact diagonalization scheme. For simplicity, we define the unperturbed single-electron Hamiltonian,

$$H_0 = \frac{\mathbf{p}^2}{2m^*} + \frac{m^*}{2} (\Omega_x^2 x^2 + \Omega_y^2 y^2) + \frac{\Delta}{2} \sigma_z \quad (3)$$

describing a two-dimensional harmonic oscillator with the renormalized frequencies $\Omega_{x,y} = \sqrt{\omega_{x,y}^2 + \omega_c^2/4}$ and the cyclotron frequency $\omega_c = eB/m^*$. In the QR case, it is supposed that $\omega_x = \omega_y = \omega$. The confinement lengths are $R_i = \sqrt{\hbar/(m^* \omega_i)}$, while the natural lengths are $\ell_i = \sqrt{\hbar/(m^* \Omega_i)}$. The eigen-state of the harmonic oscillator with its eigen function $\psi_{n_x, n_y}(\mathbf{r})$, where $n_{x,y}$ are the quantum numbers of the oscillator, is used as the basis in the numerical exact diagonalizations.

When the QD or QR contains more than one electron, the Coulomb interaction term is,

$$\mathcal{H}_C = \frac{1}{2} \sum_{i,j,k,l} \sum_{s,s'} V_{i,j,k,l} c_{l,s}^\dagger c_{j,s'}^\dagger c_{k,s} c_{l,s}, \quad (4)$$

where $c^\dagger$ is the operator of an electron, s, s' are the spin indices, and i, j, k, l stand for the collective indices, each of them contains the x, y quantum numbers of the quantum oscillator. For instance, $k = (k_x, k_y)$, $k_{x,y}$ are the quantum numbers of the oscillator in x and y directions, respectively. The Coulomb interaction matrix element $V_{i,j,k,l}$ is evaluated numerically,

$$V_{i,j,k,l} = \frac{2}{\pi \varepsilon \sqrt{\ell_x \ell_y}} \prod_{\mu=x,y} (-1)^{|j_\mu - k_\mu|} \gamma(i_\mu, l_\mu) \gamma(j_\mu, k_\mu) i^{|i_\mu - l_\mu| + |j_\mu - k_\mu|} \int_{-\infty}^{\infty} dx dy \Phi(i_x, l_x, x) \Phi(j_x, k_x, x) \frac{\Phi(i_y, l_y, y) \Phi(j_y, k_y, y)}{\sqrt{\frac{\ell_y}{\ell_x} x^2 + \frac{\ell_x}{\ell_y} y^2}}, \quad (5)$$

where ε is the dielectric constant and

$$\gamma(n, m) = \sqrt{\frac{2^{\min(n, m)} \min(n, m)!}{2^{\max(n, m)} \max(n, m)!}}, \quad (6)$$

$$\Phi(n, m, x) = x^{|n-m|} e^{-\frac{1}{2}x^2} L_{\min(n, m)}^{|n-m|} \left(\frac{x^2}{2} \right) \quad (7)$$

with the Laguerre polynomial L . Note that the nonzero integral requires that $|i_x - l_x| + |j_x - k_x|$ and $|i_y - l_y| + |j_y - k_y|$ in the integrand are even, which also guarantees that the Coulomb interaction matrix element is real.

By diagonalizing the total Hamiltonian H , the (many-body) wave function of the studied state is obtained,

$$|\Psi\rangle = \sum_{\{j\}} d_j |(j_1, s_1), (j_2, s_2), \dots, (j_{N_e}, s_{N_e})\rangle, \quad (8)$$

where N_e is the electron number and d_j is the coefficient of the many-particle (or a single-particle) basis obtained by the exact diagonalization. In the many-particle basis $|(j_1, s_1), (j_2, s_2), \dots, (j_{N_e}, s_{N_e})\rangle$, (j_n, s_n) are the indices for the n -th electron of the system, where j_n is the collective index containing the x, y quantum numbers of the quantum oscillator and s_n is the spin index. Then the interested spin fields $\sigma_\mu(\mathbf{r})$ of such a state can be defined generally by

$$\sigma_\mu(\mathbf{r}) = \sum_{\{i\}, \{j\}} d_i^* d_j \sum_{k,l,s,s'} \psi_{k,s}^\dagger(\mathbf{r}) \sigma_\mu \psi_{l,s'}(\mathbf{r}) \langle (i_1, s'_1), \dots, (i_{N_e}, s'_{N_e}) | c_{k,s}^\dagger c_{l,s'} | (j_1, s_1), \dots, (j_{N_e}, s_{N_e}) \rangle, \quad (9)$$

and the density is given by

$$n(\mathbf{r}) = \sum_{\{i\}, \{j\}} d_i^* d_j \sum_{k,l,s} \psi_{k,s}^\dagger(\mathbf{r}) \psi_{l,s}(\mathbf{r}) \langle (i_1, s'_1), \dots, (i_{N_e}, s'_{N_e}) | c_{k,s}^\dagger c_{l,s} | (j_1, s_1), \dots, (j_{N_e}, s_{N_e}) \rangle. \quad (10)$$

The wave function of $\psi_{k,s}(\mathbf{r}) = \psi_{k_x, k_y, s}(\mathbf{r})$ is a spinor, which can be written explicitly for different spins in the basis of σ_z : $\psi_{k_x, k_y, +}(\mathbf{r}) = \psi_{k_x, k_y}(\mathbf{r}) \begin{pmatrix} 1 & 0 \end{pmatrix}^T$ and $\psi_{k_x, k_y, -}(\mathbf{r}) = \psi_{k_x, k_y}(\mathbf{r}) \begin{pmatrix} 0 & 1 \end{pmatrix}^T$. These quantities are observables that can be measured experimentally.

Index characterizing the topology of the spin texture

The winding number is introduced mathematically to characterize the topology of the in-plane spin fields

$$q = \frac{1}{2\pi} \oint d\phi = \frac{1}{2\pi} \oint \frac{\sigma_x(\mathbf{r}) d\sigma_y(\mathbf{r}) - \sigma_y(\mathbf{r}) d\sigma_x(\mathbf{r})}{\sigma_x(\mathbf{r})^2 + \sigma_y(\mathbf{r})^2}, \quad (11)$$

where $\phi(\mathbf{r}) = \arctan[\sigma_y(\mathbf{r})/\sigma_x(\mathbf{r})]$. The route of the integral is a closed path around a singularity of the ϕ field. The winding number can also be written in terms of a Berry connection. Since the winding number is directly related to the topological feature of the in-plane spin field, it is therefore defined as the topological charge of the system. If the $\sigma_z(\mathbf{r})$ is also involved, such as for the skyrmion, the topological current is defined by $J_t(\mathbf{r}) = \bar{\sigma}(\mathbf{r}) \cdot (\partial_x \bar{\sigma}(\mathbf{r}) \times \partial_y \bar{\sigma}(\mathbf{r}))$, where the vector field is defined by $\bar{\sigma}(\mathbf{r}) = (\sigma_x(\mathbf{r}), \sigma_y(\mathbf{r}), \sigma_z(\mathbf{r}))/n(\mathbf{r})$. This topological current can also be written by the Mermin-Ho relation (Han, 2017). Then the charge of the topological current is given by the Pontryagin index

$$Q = \frac{1}{4\pi} \int d^2r J_t. \quad (12)$$

In a QD, the singularity of the ϕ field is usually located at the origin, while in a quantum ring, it is natural to define the integral route as the ring itself, i.e. the circle of $r = R$. However, when the magnetic field is varied, the electron density may not be concentrated exactly in the circle of the QR, so it would be convenient to define the winding number along the cycle with an arbitrary radius r' ,

$$q(r') = \frac{1}{2\pi} \oint_{r=r'} \frac{\sigma_x(\mathbf{r})d\sigma_y(\mathbf{r}) - \sigma_y(\mathbf{r})d\sigma_x(\mathbf{r})}{\sigma_x(\mathbf{r})^2 + \sigma_y(\mathbf{r})^2}. \quad (13)$$

Note that $q(r)$ could depend on r . As a result, the topological features of the QR are significantly different from those in QDs (Peng et al., 2021a). Moreover, the spin texture loses its relevance when the charge density is small at $|r - R| \gg 0$. To eliminate the textures of the spin fields with low charge density, it would be better to define a new parameter as the reduced topological charge,

$$q' = \frac{1}{2\pi} \oint_0^{2\pi} \frac{\sigma_x(\theta)d\sigma_y(\theta) - \sigma_y(\theta)d\sigma_x(\theta)}{\sigma_x(\theta)^2 + \sigma_y(\theta)^2}, \quad (14)$$

where the spin fields are integrated on r , $\sigma_{x,y}(\theta) = \int_0^\infty \sigma_{x,y}(r, \theta) r dr$. It means that the texture with the highest density in the spin fields represents the most important part of its topological feature.

Spin textures in quantum dots

As stated in the last section, the winding number in Eq. (11) of the spin fields can be evaluated analytically by the given spin fields, or be computed numerically by using the data of the spin fields in real space. By performing the integral in Eq. (11), it appears that the winding number is robust against the eccentricity of the dot. This quantity is thus defined as the topological charge which is invariant in geometry deformation. In the following, the analytical treatment of the spin fields will be discussed.

Analytical treatment for the topological charges of the spin textures

Considering that the many-body Hamiltonian may not be easy to deal with, we constrain ourselves to the single-electron case in the analytical treatment. In addition, it is also difficult to solve the Hamiltonian with the arbitrary combination of the Rashba and Dresselhaus SOC, except for the special cases $g_1 = \pm g_2$. In a straightforward way, we adopt the perturbation theory to calculate the ground state of the quantum dot. The total single-electron Hamiltonian is $\mathcal{H} = H_0 + H_p$ where the unperturbed part H_0 is given by Eq. (3), and the perturbed part is $H_p = \mathcal{H}_{L_z} + \mathcal{H}_{\text{SOC}}$ with $\mathcal{H}_{L_z} = \frac{eB}{2m^*} (xp_y - yp_x)$ and $g_{1,2}$ being small. Here we choose the symmetric gauge, $\mathbf{A} = \frac{1}{2}B(-y, x, 0)$.

This decomposition of the Hamiltonian is sufficient for arbitrary magnetic field. Naively speaking, according to the simple inequality: $\frac{p_x^2}{2m^*} + \frac{m^*}{2}(\Omega_y^2 y^2) \geq \frac{\Omega_y}{2}|p_x y| > \frac{\omega_c}{2}|yp_x|$, therefore $\langle H_s \rangle > \langle \mathcal{H}_{L_z} \rangle$ for arbitrary B . On the other hand, the energy scale of H_0 is $E_0 = \hbar\Omega_x/2 + \hbar\Omega_y/2$, and the energy scale of $\mathcal{H}_{\text{SOC}}$ is of the same order of $E_{\text{SOC}} \sim g_{1,2}\sqrt{\hbar m^* \Omega_{x,y}} \left(1 + \frac{1}{2} \frac{\omega_c}{\Omega_{x,y}}\right) < 2g_{1,2}\sqrt{\hbar m^* \Omega_{x,y}}$. Hence, $E_{\text{SOC}}/E_0 \rightarrow 0$ when the magnetic field is very large ($\Omega_{x,y} \rightarrow \infty$).

Following the standard perturbation theory, the wave function of the ground state can be calculated, so that the topological charge of the spin field defined by the winding number can be obtained (Luo and Chakraborty, 2019),

$$q = \text{sgn}(G_{1,x}^\pm G_{1,y}^\pm - G_{2,x}^\pm G_{2,y}^\pm), \quad (15)$$

where

$$G_{1,(x,y)}^\pm = \frac{(\pm 2\hbar - eB\ell_{x,y}^2)g_1}{2(|\Delta| + \hbar\Omega_{x,y})\ell_{x,y}}, \quad (16)$$

$$G_{2,(x,y)}^\pm = \frac{(\mp 2\hbar - eB\ell_{x,y}^2)g_2}{2(|\Delta| + \hbar\Omega_{x,y})\ell_{x,y}}. \quad (17)$$

Note that $\pm$ is for different sign of Landé g factor, since the unperturbed wave functions are different. When $g > 0$, $+$ is chosen in the formula of q , and $-$ is chosen for $g < 0$. The topological properties of the spin field in the QD hydrogen are then clear. The winding number is robust against the ellipticity of an anisotropic dot, so it can be defined as the topological charge of the spin field.

As mentioned before, the spin can also be textured by the external inhomogeneous magnetic field (or magnetic domains (Nagase et al., 2021)). The topological properties of the spin field can be obtained without the wave function in some cases. If the magnetic field itself has a topological non-trivial pattern, it can be found that (Naseri et al., 2020),

$$\sigma_y(\mathbf{r})B_x(\mathbf{r}) = \sigma_x(\mathbf{r})B_y(\mathbf{r}), \quad (18)$$

which indicates that the in-plane spin textures exactly follow the texture of the in-plane magnetic fields, when the system has the symmetry, $[\mathcal{H}, \frac{-i}{N}\partial_\theta + \frac{\sigma_z}{2}]$ where N is an integer related to the winding number and θ is the angular coordinate of the plane. The winding number is then obtained by the in-plane magnetic field. If such a rotational symmetry does not exist, then a Wentzel-

Fig. 1 The spin textures in a QD hydrogen with the size parameters $R_x = R_y = 15$ nm (the Zeeman coupling coefficient $\Delta < 0$) at $B = 0.1$ T. The parameters of the material are taken as those in InAs (Luo et al., 2019). (A) For Rashba SOC only, $\hbar g_r = 40$ nm·meV, and (B) for Dresselhaus SOC $\hbar g_d = 20$ nm·meV only. Hereafter, unless otherwise specified, the colors of the two-dimensional pictures represent the density of the electron, which is defined by Eq. (10), and the arrows represent the in-plane vectors $(\sigma_x(\mathbf{r}), \sigma_y(\mathbf{r}))$ where the spin fields $\sigma_{xy}(\mathbf{r})$ are given in Eq. (9).

Kramers-Brillouin (WKB) approximation can be applied. Expand the spin fields in series of the power of a supposed small quantity $\omega_{co} = \hbar\omega_d/E$ where E is the eigenenergy of $\mathcal{H}$ (weak magnetic field) $\sigma_j(\mathbf{r}) = \sum_{n=0}^{\infty} \omega_{co}^n \sigma_j^{(n)}(\mathbf{r})$. Substitute it into the continuity equation and the relation between the lowest few orders of the spin fields and the magnetic fields are obtained. Hence, some properties of the spin fields can be found without explicitly solving the Schrödinger equation.

Control of the topological charge of the spin textures and the effect of inhomogeneous magnetic field

With Rashba/Dresselhaus SOC in a quantum dot hydrogen, the topological charge is apparently according to Eq. (15): $q = 1$ for the case that only Rashba SOC is present while $q = -1$ for the case that only Dresselhaus SOC exists, as shown in Fig. 1. The spin textures associated with different topological charges are described as follows: The vector $(\sigma_x(\mathbf{r}), \sigma_y(\mathbf{r}))$ of the in-plane spin rotates clockwise by $2m\pi$ if we move around the center of the dot in a clockwise direction, hence, with the winding number $+m$; If we move around the center in a clockwise direction, then the in-plane spin field rotates anticlockwise by $2m\pi$ leading to a winding number $-m$.

In fact, these spin textures are similar to those in a free two-dimensional electron gas with Rashba and Dresselhaus SOC in momentum space. To see this point, consider the Hamiltonian $\bar{H}_R = \mathbf{p}^2 + \sigma_x p_y - \sigma_y p_x$, which commutes with the momentum operators. Thus the momentum operators can be replaced by the wave vector of the kinetic momentum k_x, k_y . To minimize the energy, the spin field in the momentum space $(\sigma_x(\mathbf{k}), \sigma_y(\mathbf{k}))$ must be anti-parallel to the vector $(k_y, -k_x)$, i.e., $(\sigma_x(\mathbf{k}), \sigma_y(\mathbf{k})) \propto (-k_y, k_x)$ which is simply a vortex with $q = 1$ having a global phase difference from the vortex in the spin field in real space. If the Hamiltonian contains only the Dresselhaus SOC, $\bar{H}_D = \mathbf{p}^2 + \sigma_y p_y - \sigma_x p_x$, then the spin field in the momentum space $(\sigma_x(\mathbf{k}), \sigma_y(\mathbf{k})) \propto (k_x, -k_y)$ has $q = -1$.

The topological charge is tunable, basically according to Eq. (15), by tuning the external parameters, when both SOC are present. Note that the topological charge is not determined simply by the magnitudes of $|g_1|$ and $|g_2|$. The straightforward way is to tune the SOC directly: if the magnetic field is fixed, the topological charge tends to be $+1(-1)$ when the strength of the Rashba (Dresselhaus) SOC is dominant in the SOC. The Rashba SOC can be simply changed by the gate (Nitta et al., 1997; Kohda et al., 2008; Ast et al., 2008; Kanai et al., 2011), while the Dresselhaus may depend more on the material itself. Nevertheless, the ratio of the Rashba SOC to the Dresselhaus SOC can be tuned in a wide range, for instance in the InAs QDs, by an in-plane magnetic field (Nowak et al., 2011).

According to Eq. (15), when both SOC exist, tuning the magnetic field may also change the topological charge of the system. It is because the topological charge is related to the sign of the Landé g factor of the material

$$q = -\text{sgn}(g), \quad (19)$$

when $B \rightarrow \infty$ (Luo and Chakraborty, 2019). If a QD holds the topological charge of the spin field to be $q = \text{sgn}(g)$ for small magnetic fields, then q must be opposite by increasing the magnetic field. Examples are shown in Fig. 2.

Although the spin fields are observable quantities and the first step in this direction has been experimentally achieved — plotting the charge density of a single electron in a QD (Camenzind et al., 2019), the textures of the spin fields, however, are not so easy to be observed thus far. An indirect measurement was proposed by measuring another observable quantity $\langle \sigma_z \rangle$ via magnetometry or optically pumped NMR measurements (Dementyev et al., 2001; Kuzma et al., 1998; Barrett et al., 1995). It is because that the topological charge may be related to the sign of $\langle \sigma_z \rangle$. Consider a QD coupled by a single spin-orbit interaction (Rashba or Dresselhaus) in a perpendicular magnetic field pointing up, the sign of $\langle \sigma_z \rangle$ is always opposite to the sign of g when the magnetic field is strong enough to polarize the whole spin field. However, the sign of $\langle \sigma_z \rangle$ of the electron may be reversed with decrease of the magnetic field when the QD is sufficiently large.

Two cases for the sign of $\langle \sigma_z \rangle$ identifying the topological charge: (i) For the negative Landé g factor material, $\langle \sigma_z \rangle > 0$ in presence of a strong magnetic field. But the Dresselhaus SOC is able to convert the sign of $\langle \sigma_z \rangle$ to negative in a weak magnetic field in a large QD; (ii) For the positive Landé g factor QD, $\langle \sigma_z \rangle < 0$ in a strong magnetic field. But the Rashba SOC is able to convert the sign of $\langle \sigma_z \rangle$

Fig. 2 The evolution of spin textures in QDs with magnetic fields in different materials. The magnetic fields are (A) $B = 0.1$ T, and (C) $B = 10$ T for an InAs dot, and (B) $B = 0.1$ T, (D) $B = 10$ T for a ZnO dot. In both dots $R_x = 15$ nm, $R_y = 14$ nm. The SOC's are $\hbar g_1 = \hbar g_2/2 = 10$ meV·nm for the InAs dot, and $\hbar g_1 = 2\hbar g_2 = 5$ meV·nm for the ZnO dot. The Landé g factors are negative and positive for the two materials, InAs and ZnO, respectively. (E) The winding numbers of the two cases. For the InAs QD, $q = 1$ at large magnetic field, while $q = -1$ for the ZnO QD, due to Eq. (19) (Luo and Chakraborty, 2019).

Fig. 3 The average values of the σ of the ground states in InAs QDs. (A) $\langle \sigma_z \rangle$ in a single-electron InAs QD ($R = R_x = R_y = 15$ nm) without SOC, with Rashba SOC only ($\hbar g_1 = 40$ nm·meV), and with both the two SOC's ($\hbar g_1 = 40$ nm·meV, $\hbar g_2 = 20$ nm·meV). The stronger SOC's are, the spin is more unpolarized. (B) The sign of $\langle \sigma_z \rangle$ in a large InAs dot is flipped in weak magnetic field when the Dresselhaus SOC is present for a negative Landé g factor material. Here g_1 and g_2 are given in units of nm·meV/h (Luo et al., 2019).

to positive in a weak magnetic field when the size of the QD is large enough. Since the size of the QD can be tuned by the gate, one could identify the type of SOC in the QD system by measuring if the sign of $\langle \sigma_z \rangle$ is changed or not while increasing the external magnetic field.

If both SOC's are present, the general flipping condition of $\langle \sigma_z \rangle$ can also be understood by the perturbation calculations. As a first step, compute the second-order perturbed energies $E_{\pm}^{(2)}$ based on the two unperturbed states $\psi_{0,0,+}$ and $\psi_{0,0,-}$, respectively. Then compare the two energies $E_{\pm} = E_{\pm}^{(0)} + E_{\pm}^{(2)} = \pm \Delta/2 + E_{\pm}^{(2)}$. The lower one determines the ground state and its spin polarization: $\langle \sigma_z \rangle > 0$ for E_+ and $\langle \sigma_z \rangle < 0$ for E_- .

For instance, we consider an InAs QD with $m^* = 0.042m_e$, and the Landé factor $g = -14$, then $E_+ < E_-$ always if only the Rashba SOC is present, which means that $\langle \sigma_z \rangle > 0$ whatever the strength of the magnetic field is. However, E_+ could be larger than E_- for a large QD if only the Dresselhaus SOC exists, which means that the ground state is with E_- and $\langle \sigma_z \rangle < 0$ in a weak magnetic field. In a strong magnetic field, the spin polarization would be forced to be parallel to the magnetic field $\langle \sigma_z \rangle > 0$ since $g < 0$. $\langle \sigma_z \rangle$ is thus flipped in a critical magnetic field. The numerical simulation also supports this phenomenon as shown in Fig. 3.

Another possible way to texture the spin is to put the quantum dot in the textured external magnetic field. The spin would be formed generally following the pattern of the magnetic field. Some examples are given in Ref. (Naseri et al., 2020). It is worth mentioning that the topological soliton, skyrmion, can be generated in a special magnetic field

$$\mathbf{B}_{sk} = B_0 \left(\frac{2\kappa R_{sk}x}{r^2 + (\kappa R_{sk})^2}, \frac{2\kappa R_{sk}y}{r^2 + (\kappa R_{sk})^2}, \frac{r^2 - (\kappa R_{sk})^2}{r^2 + (\kappa R_{sk})^2} \right), \quad (20)$$

where a dimensionless parameter κ and a constant with a dimension of length R_{sk} controls the size of the skyrmion. Further numerical calculations show that the ground state is a skyrmion with topological charge $Q = -1$, as well as the first and the second excited states, as shown in Fig. 4. However, the third excited state is no longer a skyrmion.

Fig. 4 In-plane spin textures presented by arrows and the colors represent $\sigma_x(\mathbf{r})$ for the magnetic field $\mathbf{B}_{sk}$ with the isotropic confinement $\hbar\omega_x = \hbar\omega_y = 5$ meV. In $\mathbf{B}_{sk}$, $B_0 = 7$ T, $\kappa = 0.3$, and $R_{sk} = 1.9 R_x = 1.9 R_y$ (Naseri et al., 2020). In-plane spin textures in all the eigenstates have $q = 1$. Moreover, the ground-state, the first, and the second excited states have a Pontryagin index $Q = -1$ [shown in panels (A), (B), and (C), respectively]. (D) However, the third excited state has no skyrmion spin textures.

When the magnetic field has the topologically trivial pattern as $\mathbf{B} = (B_x, 0, B_z)$, the spin fields of the electron in a QD may still be topologically nontrivial. In a WKB analysis, the quantum corrections beyond the Landau-Lifshitz-Gilbert equation would generate the y component of the spin fields $\sigma_y(\mathbf{r}) \neq 0$ even for $B_y = 0$. An example was shown in Ref. (Naseri et al., 2020): A topologically trivial magnetic field $\mathbf{B}_m = B_0 ((br)^{|m|} \cos(m\theta), 0, 1)$, where b is a dimension of inverse length, is applied to an isotropic QD. The winding number of the in-plane spin field is given by $q = \pm \text{msgn}(F_x F_y)$, where $\pm$ is taken for different eigen states and $F_{x,y}$ are the radial part of the spin fields $\sigma_{x,y}(\mathbf{r})$, respectively. Interestingly, some discontinuous magnetic fields as magnetic domains are also able to induce topological nontrivial spin textures with different topological charges for different eigenstates.

The inhomogeneous magnetic fields, whether they are continuous or discontinuous, can be realized by a modulated external magnetic field or be manufactured in some magnetic materials with different magnetic domains. Due to the extraordinary pattern, the inhomogeneous magnetic field can make the spin field in the QD hold higher topological charge, while the Rashba and linear Dresselhaus SOC's can only induce topological charge $q = \pm 1$.

Spin textures in quantum dot helium

In this subsection, we discuss how the Coulomb interaction affects the topological properties in an isotropic quantum dot helium (Luo and Chakraborty, 2019). It seems that no suitable analytical method is available in this case and we only discuss the exact diagonalization results of the spin textures and an important quantity, the z component of the angular momentum L_z characterizing the rotational symmetry of the system. The spin textures and the density profile are closely dependent and influence each other due to the existence of the Coulomb interaction. The density profile is related to $\langle L_z \rangle$, so the spin textures are related to $\langle L_z \rangle$ as well.

Note that $\langle L_z \rangle$ is quantized and evolves stepwise (akin to a first-order phase transition) by the Coulomb interaction with increase of the magnetic field if there is no SOC, and plateaus of the curve of $\langle L_z \rangle$ are discontinuous. When the SOC is present, then the curve of $\langle L_z \rangle$ still grow stepwise, but between the two plateaus the curve is no longer discontinuous, which is akin to a second-order phase transition. If only one SOC is present then the density profile looks still rotationally invariant, and the spin textures are mainly determined by the SOC, similar to those in the single-electron case.

When both the SOC's are present, overall the density profile evolves with the change of $\langle L_z \rangle$. The density has (almost) the rotational symmetry when $\langle L_z \rangle$ is (almost) an integer since L_z commutes with rotation with respect to the z axis, i.e. the density

Fig. 5 Evolution of the density profiles of an InAs QD helium. The size of the QD is given by $R_x = R_y = 15$ nm. The SOC's are $\hbar g_1 = \hbar g_2 = 20$ nm-meV. The magnetic fields are gradually increased: (A) 1 T; (B) 3.7 T; (C) 6 T; (D) 12 T; (E) 17.5 T; (F) 18 T; (G) 23 T. The Roman numerals are corresponding to the states marked in panels (A) to (G) and explained in the text of Ref. (Luo and Chakraborty, 2019).

profile is a dot-shape or a ring-shape for $\langle L_z \rangle$ locating at the plateau near an integer. But the two SOC's accompanied by the Coulomb interaction make $\langle L_z \rangle$ deviate from the integer in the region between the plateaus, where the density of the electrons is stretched or split. The evolution of the density profile with increase of the magnetic field comes to a split-merge cycle, as shown in Fig. 5.

Since there may be more than one vortices appearing in the spin textures, for instance in Figs. 5B–E, a new term, the overall winding number (OWN) is introduced to characterize the topological charge of the spin fields. The OWN can be obtained in Eq. (11) by choosing the contour of the integral around the edge enclosing all the possible vortices. It can also be obtained by summing the topological charge for each vortex in the enclosed contour. It is obvious that the OWN still obeys the relation Eq. (19) when B is strong.

We note that the topological features are tunable by adding electron in the system. Consider a InAs dot with $\hbar g_1 = \hbar g_2 = 20$ meV-nm, the sign of the topological charge is altered in the QD helium by the many-body effect as shown in Fig. 6A. The ranges of the topological charge changes for the QD helium (comparing with the cases of QD hydrogen) are open when $\langle L_z \rangle$ is converted from 0 to -1 and $\langle \sigma_z \rangle$ is converted from 0 to 2. Since $\langle L_z \rangle$ is not observable in a magnetic field, the topological inversion can be traced into the region where $0 < \langle \sigma_z \rangle < 1$, which provides the clue for indirectly measuring the topological charge.

Spin textures in quantum rings

In this section the quantum ring systems with a single electron and two SOC's are discussed. The spin textures in the QRs should be very different from those in quantum dots due to the geometry differences and the existence of the magnetic flux. The windings of the spin fields in the QRs are in fact included as part of the nonadiabatic Aharonov-Anandan geometric phase (Aharonov and Anandan, 1987) and are related to the Aharonov-Casher phase (Frustaglia and Nitta, 2020). Therefore, the study of the spin textures also promotes the study of the transport issue in QR systems (Physics of Quantum Rings, 2018; Frustaglia and Richter, 2004; Peng et al., 2021b). The topology of the spin field may no longer be robust against the ellipticity of the ring, which takes new textures on the spin fields. Moreover, the quantum ring can be doped and the effect of the impurity to the spin textures will be introduced.

Various spin textures in QRs

The analytical treatment of a QR with SOC's can be simplified by considering a one-dimensional (1D) ring with zero width, when the ring is narrow. The winding number q is thus calculated by using the spin fields obtained in the 1D model. The Hamiltonian of the 1D model reads

$$H_{1D} = \left[-i \frac{\partial}{\partial \theta} + N + \beta_1 \sigma_r(\theta) + \beta_2 \sigma_\theta(-\theta) \right]^2 - (\beta_1^2 + \beta_2^2 + 2\beta_1\beta_2 \sin 2\theta) + \beta_3 N \sigma_z, \quad (21)$$

Fig. 6 (A) The overall winding number of the QDs helium: $R_{x,y} = 15$ nm, $\hbar g_{1,2} = 20$ nm·meV for the InAs dot; and $R_{x,y} = 15$ nm, $\hbar g_{1,2} = 5$ nm·meV for the ZnO dot, comparing with the OWNs of the QDs hydrogen with the same SOC. The arrows show the OWN reversed by adding an electron. (B) The OWN, (C) $\langle L_z \rangle$, and (D) $\langle \sigma_z \rangle$ for the InAs QD helium with tuning $\hbar g_1 \in [0, 20]$ meV·nm and fixed $\hbar g_2 = 20$ meV·nm. (E) In comparison, these quantities of the ground state of the two non-interacting electrons are also plotted (Luo and Chakraborty, 2019).

where $\sigma_r(\theta) = \sigma_x \cos \theta + \sigma_y \sin \theta$, $\sigma_\theta(\theta) = \sigma_y \cos \theta - \sigma_x \sin \theta$, $\beta_{1,2} = \frac{g_{1,2} m^* R}{\hbar}$ specify the dimensionless Rashba SOC and Dresselhaus SOC strengths, respectively, $N = \frac{e B r_0^2}{2\hbar}$ is the relative magnetic flux threading the area of the ring, and $\beta_3 = g \frac{m^*}{m_e}$ describes the dimensionless Zeeman energy.

If the magnetic field is absent, the Hamiltonian can be simplified to

$$H_{1D} = \left[-i \frac{\partial}{\partial \theta} + M(\theta) \right]^2 - [M(\theta)]^2, \quad (22)$$

where $M(\theta) = A(\theta)\sigma_x + B(\theta)\sigma_y$ with $A(\theta) = \beta_1 \cos \theta + \beta_2 \sin \theta$ and $B(\theta) = A(\pi/2 - \theta)$. Therefore, A and B represent the x and y component of the effective magnetic field induced by the SOC, respectively. Suppose that the wave function can be written by $\Psi(\theta) = f(\theta)\chi(\theta)$, where f is a scalar function and χ is a spinor function. From the Schrödinger equation $H_{1D} \Psi = E_{1D} \Psi$, one obtains

$$(-M^2 - E_{1D})f - \frac{\partial^2 f}{\partial \theta^2} = 0, \quad (23)$$

$$\frac{\partial \chi}{\partial \theta} + iM\chi = 0. \quad (24)$$

Eq. (23) is the well-known Mathieu equation determining the relation between the energy of the state and the magnetic field, and the density of electron $|f|^2$, which agree with the results obtained by Lía and Tamborenea (2021)). Eq. (24) determines the spin fields and the associated topological charge.

When observing the spin in the radial direction from the origin to infinity, the spin rotates as a spiral in the plane perpendicular to the xy plane where the electron is confined with the Rashba SOC being present. In an elliptical QR, different position in the ring has different radial length (from the origin, the center of the ellipse), so the angle between the spin orientation and the xy plane in different position of the ring may be different, while in a circular ring this angle is the same everywhere. For this reason, Ying et al. (Ying et al., 2016) found that in an elliptical QR with Rashba SOC, the spin fields can be textured to carry different topological charges. When the strength of the SOC increases or the ellipse ratio decreases, the spin precesses more along the ring, as shown in Fig. 7 (Ying et al., 2016).

Another way to tune the topological charge in the QR is to introduce the in-plane magnetic field (Henri Saarikoski et al., 2015; Baltanás et al., 2017; Wang et al., 2019). The spin field is textured by the Rashba SOC in a way that the spin orientation points toward or backwards to the center with rotational symmetry to the z axis. However, an in-plane magnetic field is able to break this symmetry to force the spin parallel to the direction of this magnetic field. Considering the continuity of the spin field as discussed in Section “Control of the topological charge of the spin textures and the effect of inhomogeneous magnetic field”, the spin textures may be varied to carry different winding numbers. Some cases are shown in Fig. 8. for different Rashba SOC and in-plane Zeeman couplings (Henri Saarikoski et al., 2015).

Tuning either the deformation of the QR or the in-plane magnetic field one can control the topology of the spin fields of the QR. Another straightforward way is to tune the SOC directly. Sheng and Chang (Sheng and Chang, 2006) obtained analytically the

Fig. 7 The spin textures in an elliptical ring with the ratio of semi-minor axis to the semi-major axis 0.4. (A) to (F) Evolution of the spin orientation on the Bloch sphere and the spin textures in the elliptical ring with varying the Rashba SOC strengths given in Ref. (Ying et al., 2016). When the Rashba SOC is increased the winding of the spin field is also possibly increased.

Fig. 8 Different phases are indicated for a transport problem in a QR system (Henri Saarikoski et al., 2015). Among these phases, the spin textures are closely related to the Aharonov-Anandan geometry phase. The spin textures at three selected points (cases A, B and C) are displayed in the right lower panel.

eigen states of the QR when one SOC is present in a perpendicular magnetic field. Similar to the QD, the topological charge of the QR with a single SOC is +1 (Rashba) or -1 (Dresselhaus), and the spin textures are also similar to those in Fig. 1, but only concentrated on the 1D ring (Sheng and Chang, 2006), as illustrated in Fig. 9. It would be reasonable to assume that the topological transition from $q = +1$ to -1 (or -1 to $+1$) could occur when both the Rashba and Dresselhaus SOC are present. This transition will be discussed in the next subsection.

Aharonov-Bohm Period of the topological charge of the QR

Here again, the Hamiltonian with both SOC can be solved by the perturbative theory, where the topological features of the spin fields in a QR would be very different. It has been shown that the topological transition occurs at (Peng et al., 2021a)

$$\eta = \frac{1}{2} - \frac{2\beta_3 N(N-l')}{4(N-l')^2 - 2|\beta_3 N| - 1}, \quad (25)$$

where $l' = \lfloor N + \frac{1}{2} \rfloor$, $\eta = \frac{|\beta_1|}{|\beta_1| + |\beta_2|}$, and $\lfloor \dots \rfloor$ represents a floor function. The topological transition lines are shown in Fig. 10. It is clear that the topological charge is varied periodically when the magnetic field is increased as a result of the Aharonov-Bohm (AB) effect. The period of the topological charge is exactly identical to the AB period in the 1D model.

In a QR of finite width, numerical calculations show that the 1D model is generally correct, especially when the width is not too large. However, with the increase of the width, the spin textures in a QR gradually evolves into the case of a QD, as shown in Fig. 11. The period of the topological charge is then no longer a constant AB period but is modified a bit by the finite width. To qualitatively understand the width effect, we can use an effective radius of the ring, $R' = \int n(r, \theta) r^2 dr d\theta$ where $n(r, \theta)$ is the density of the electron, in the 1D model. Moreover, flipping of $\langle \sigma_z \rangle$ in a QD also exists in the QR, accordingly. Since the radius of the ring can be largely tuned, spin rotation in the radial direction is also observed in a QR, which is absent in the 1D model with zero width (Peng et al., 2021a).

Fig. 9 The illustration of the spin textures for the 1D ring, (A) with Rashba SOC only and (B) with Dresselhaus SOC only.

Fig. 10 The topological transition critical lines given by Eq. (25) for (A) $\beta_3 = -0.588$ and (B) $\beta_3 = 0.588$. In the regions above the critical lines the topological charge is $q = 1$, while the regions with $q = -1$ are below the critical lines (Peng et al., 2021a).

Fig. 11 The in-plane spin textures, spin density $\sigma_z \langle \mathbf{r} \rangle$ and the topological charges q' in a narrow InAs QR [panels (A), (C), (E)], and in a wide InAs QR [panels (B), (D), (F)], respectively. $\alpha = \sqrt{\frac{\hbar}{2m^* \omega R^2}}$ describes the ratio of ring width to radius R . The system approaches the 1D model when $\alpha \rightarrow 0$. The relative magnetic flux $2N \in \mathbb{Z}$ are marked by black vertical dotted lines in (C) and (D). The period of the topological charge is no longer the constant of the AB period with increase of the magnetic field due to the width effect of the ring.

Higher topological charge due to the impurity

In a non-symmetric QR where a non-magnetic impurity is located, the density and the spin textures of the single-electron ground state jointly make a dramatic change comparing with the 1D model where the radial degree of freedom is neglected. The impurity can be treated as an external potential for which the Hamiltonian is (Chakraborty and Pietiläinen, 1995b)

$$H_I = \frac{1}{2} m^* \omega^2 R^2 \gamma e^{-\frac{(x-R)^2 + y^2}{\delta^2 R^2}}, \quad (26)$$

where γ and δ are tunable dimensionless parameters characterizing the size of the impurity. Without loss of generality, the impurity is supposed to be located at $(R, 0)$. The non-magnetic impurity does not interact with the spin directly, but it does deform the density distribution of the electron. According to the theory discussed in the QD helium system in Section “Spin textures in quantum dot helium”, the density modification certainly redistribute the spin textures.

In a QR, $\langle L_z \rangle$ also change stepwise by the magnetic field due to the AB effect. The ring with an impurity no longer has the rotational symmetry. As compared to the QD helium, it is also meaningful to explore $\langle L_z \rangle$ here, since the density profile would be dramatically changed when $\langle L_z \rangle$ is deviated from an integer.

Due to the fact that the density distribution of the electron may be deviated from the minimum of the ring potential, it would be better to use q' to define the topological charge of the spin fields, which eliminates the radial effect. As shown in Fig. 12, the

Fig. 12 The InAs QR with the radius $R = 30$ nm, the confinement $\hbar\omega = 10$ meV, includes an impurity ($\gamma = 0.02$ and $\delta = 0.3$). The in-plane spin textures of the ground state with Rashba SOC only ($\hbar g_1 = 10.0$ nm·meV) at (A) $B = 1.25$ T and (C) $B = 1.05$ T, respectively. For the cases with Dresselhaus SOC only ($\hbar g_2 = 10$ nm·meV), the in-plane spin textures of the ground state at (B) $B = 3.0$ T and (D) $B = 3.5$ T, respectively. q' and $\langle L_z \rangle$ are varied in different magnetic fields, (E) with the Rashba SOC, and (F) with the Dresselhaus SOC, $q' = \pm 2$ when $\langle L_z \rangle$ varies drastically. (G) The persistent current I for (E) and (F). The yellow shadow represents higher topological charge $q' = -2$ and the blue one represents $q' = 2$.

topological charge q' can reach up to ± 2 at the single-electron level by tuning the magnetic field, which indicates a great advantage over other systems in potential applications.

A simple scenario can intuitively explain why the higher topological charges appear. Suppose that the spin texture in the ring has a charge $+1$ for the Rashba SOC. Once an impurity is added, it forms an extra quantum dot locally, which also carries a topological charge $+1$. Therefore the total local topological charge of the ring can be simply obtained by the summation $q' = +1 + 1 = +2$. The same analysis is also available for the Dresselhaus SOC, where the local topological charge $q' = -1 - 1 = -2$ can be obtained.

It is worth mentioning that $q' = \pm 2$ occur only in the regions where the persistence current dramatically changes, marked as the shadowed regions in Fig. 12G. For the QR with Rashba SOC, $q' = +2$ appears when the current is positive, while $q' = -2$ only appears when the current is negative for the QR with Dresselhaus SOC. According to this correspondence, the higher topological charge may be identified experimentally by measuring the current, however, in an indirect way.

Conclusion

In this chapter, we have reviewed the spin textures in quantum dots and quantum rings. The Rashba and Dresselhaus spin-orbit couplings texture the spin fields with different topological charge $q = \pm 1$ in a confined system in real space. In an inhomogeneous

magnetic field which can be manufactured by the modulating external magnetic field or using magnetic domains, the different topological charge of in-plane spin fields as well as the skyrmion spin textures can be obtained. The Coulomb interaction in a quantum dot dramatically changes the density distribution associated with the spin textures of the electrons when $\langle L_z \rangle$ is biased from an integer. This phenomenon is also found in the quantum ring with a nonmagnetic impurity, where higher topological charges can be achieved. We also discuss how to observe the topological properties of the system, in which the indirect ways are proposed if the direct measurement is difficult.

Abstract

We study the model of a noninteracting spinless electron gas confined to the two-dimensional localized surface of a cone in the presence of external magnetic fields. The localized region is characterized by an annular radial potential. We write the Schrödinger equation and use the thin-layer quantization procedure to calculate the wavefunctions and the energy spectrum. In such a procedure, it arises a geometry-induced potential, which depends on both the mean and the Gaussian curvatures. Nevertheless, since we consider a ring with a mesoscopic size, the effects of the Gaussian curvature on the energy spectrum are negligible. The magnetization and the persistent current are analyzed. We observed the Aharonov–Bohm (AB) type oscillations. The finite ring width has a fundamental role in the oscillatory behavior found in physical properties as a function of the magnetic field. In general, the role of curvature is to increase the amplitude of oscillations. Nevertheless, in a system with few electrons, an adequate choice of the parameters a_1 and a_2 allows for observing the effect of the geometric potential on the physical properties.

Key points

- A particle on a curved surface experiences a potential geometric which depends on the mean and Gaussian curvatures.
- The curvature, in general, shifts the energy spectrum to higher values of energy.
- The curvature increases the amplitudes of AB-type oscillations of the magnetization and persistent current.
- A wide ring with few electrons allows for observing the effect of the geometric potential on the physical properties.

Introduction

The physics of mesoscopic systems is a remarkable field of theoretical and experimental research. There are a variety of physical phenomena observed in this regime. Among them, we mention the oscillations of the magnetoresistance in a ring as a function of the magnetic field, an interference effect that corresponds to the Aharonov–Bohm (AB) effect (Aharonov and Bohm, 1959) in the condensed matter (Washburn and Webb, 1986; Beenakker et al., 1991; Liu et al., 1993). If a ring encloses a magnetic flux Φ , it carry an equilibrium current, the so-called persistent current (Büttiker et al., 1983; Lévy et al., 1990; Mailly et al., 1993; Chakraborty and Pietiläinen, 1994). In an ideal system 1D ring, this current is periodic in the AB flux Φ with a period Φ_0 , which corresponds to the flux quantum. However, in rings with finite widths, the oscillations are aperiodic due to the penetration of the magnetic field into the conducting region (Tan and Inkson, 1999). In a conducting sample through which an electric current is driven, a magnetic field normal to the direction of current flow results in two fascinating phenomena: the quantum Hall effect and the Shubnikov–de Haas oscillations (SdH) (Heinzel, 2006; Ihn, 2010). Another physical phenomenon observed in mesoscopic samples is the de Haas–van Alphen (dHvA) effect. This effect corresponds to the oscillations in the magnetization as a function of the magnetic field (Sivan and Imry, 1988; Schwarz et al., 2002; Feng and Jin, 2005; Kishigi and Hasegawa, 2021). The conductance in quantum dots shows sharp resonances as a function of the gate voltage. Between these conductance peaks, there are regions of zero conductance. This behavior is a manifestation of the Coulomb blockade, a phenomenon that arises due to the Coulomb repulsion between electrons (Kouwenhoven et al., 2001; Reimann and Manninen, 2002; Paul, 2003; Heinzel, 2006; Ihn, 2010). Mesoscopic systems also have attracted interest due to potential device applications (Kushwaha, 2001; Heinzel, 2006; Das, 2010; Ihn, 2010; Fomin, 2014). For instance, we mention the research fields of technological applications involving the optical size-dependent properties of quantum dots which leads to optimized color emission on LCD screen televisions (QLED) (Mezrag et al., 2016) and probes for

the detection of both cancer and viral infection biomarkers (Mousavi et al., 2022; Wagner et al., 2022). Moreover, there are several current investigations on the applicability of quantum dots as a system performing a *qubit* (Zhang et al., 2018; Scarlino et al., 2022), the basic unit of information in quantum computation.

Within the past few years, there has been a growing experimental interest in fabricated conducting nanostructures with two-dimensional electron gas on a curved surface (Prinz et al., 2000, 2001). These types of structures have the potential for an enormous variety of applications as basic structures for nanomechanics, nanoelectronics, and photonics as well as in biochemistry and medical sciences (Prinz et al., 2001). Motivated by the possibility of fabricated curved electronic devices, some authors investigated electronic motion in these geometry immersed in magnetic fields and reported curvature effects in magnetotransport properties (Lorke et al., 2003; Mendach et al., 2006; Vorob'ev et al., 2007; Friedland et al., 2007). The influence of a uniform external magnetic field on electronic behavior in curved samples is spatially nonuniform because only the normal-to-surface component of the magnetic field affects the electronic movement. Interestingly, the physics of a two-dimensional electron gas (2DEG) subjected to a nonuniform magnetic was treated even in the last century and motivated the production of nonplanar 2DEG (Leadbeater et al., 1995). Theoretically, the method employed to address motion of electrons on curved surfaces follows the well-known thin-layer quantization procedure employed by da Costa (1981, 1982). Ferrari and Cuoghi (2008) extend the formalism developed by da Costa for including the effect of the magnetic field and the electric field, while Wang et al. (2014) derive the Pauli equation for a charged spin particle. The da Costa method is widely used in the literature (Bulaev et al., 2004; Furtado et al., 2007; Liang et al., 2018; Wang et al., 2017; Wang and Zong, 2016; Chang et al., 2013; Gaididei et al., 2014; Zhang and Vishwanath, 2010; Teixeira et al., 2019; Atanasov and Dandoloff, 2016; Santos et al., 2016; Schmidt, 2019; Pandey et al., 2018). An interesting result that emerges from the thin-layer quantization procedure is that a particle on a curved surface experiences a potential of purely geometric origin which depends on the mean and Gaussian curvatures, which takes into account the quantum nature of the particle. Thus, even in the absence of interactions of any nature, the particles cannot move around freely on the surface.

The aim of this work is to analyze the way how the spectrum, magnetization, and persistent current depend on the device geometry and the curvature. Quantum rings can be narrow, quasi-one-dimensional objects, or also can be wide, like a quantum dot with a small hole in the center that leads to a nontrivial topology. The electronic properties, determined by the energy spectrum, are very different in these limiting cases (Kurpas et al., 2013). We consider noninteracting spinless electron gas bound to a two-dimensional localized region in the presence of external magnetic fields. The electrons are confined on a conical curved surface. The experimental analysis of semiconductors with conical geometry can be found. For example, Cao et al. (2005) reported the growth of Si and Ge nanocones, with the controlling of the apex angles. Another experimental work involving nanocones was reported by Medvid' (2012). Making use of a new laser method, Medvid carried out the formation of nanocones on the surface of elementary semiconductors Si and Ge and semiconductor solid solutions $\text{Si}_{1-x}\text{Ge}_x/\text{Si}$ and $\text{Cd}_{1-x}\text{Zn}_x\text{Te}$. These experimental reports suit as a paradigm for the theoretical analysis of the electronic behavior in these curved devices. Although the role of the electron–electron interaction is an important topic, here this effect is neglected. The study by Chakraborty and Pietiläinen (1994) outlines how the electron–electron interaction affects magnetization in narrow and wide rings. Maksym and Chakraborty (1990) studied the role of electron–electron interactions in the eigenstates of electrons in quantum dots. Recently Pereira et al. (2019, 2021) investigate the physical implications caused by curvature effects on the magnetization and persistent currents in a quantum dot and a 2D ring containing a large number of electrons. Thus, this work focuses on analyzing the effects of curvature on magnetization and persistent current in quantum rings containing few electrons. Quantum rings with few electrons have been investigated, for example, by Lorke et al. (2000) and Lei et al. (2010). In particular, Kleemans et al. (2007) report the direct measurement of the persistent current carried by a single electron by means of magnetization experiments on self-assembled InAs/GaAs quantum rings.

The remainder of this chapter is arranged as follows: In Section “Radial potential,” we present the radial potential proposed by Tan and Inkson. In this section, we also present the two rings used in the numerical analyses. We consider quantum rings of the order of 10 nm in size. This limit is of particular interest because they make it possible to study quantum rings in the true quantum limit (Lei and Lorke, 2013). In Section “Description of the model,” we use the model proposed by Tan and Inkson to constrain the motion of the electrons to an annular region. By employing the thin-layer quantization procedure, we obtain the Schrödinger equation (Ferrari and Cuoghi, 2008), and solve it to find the energies and wave functions of the electrons on the two-dimensional localized curved surface. In Sections “Electronic states,” “Magnetization,” and “Persistent current,” we present numerical results for the energy, magnetization, and persistent current, respectively. In numerical results, we assume that there is no AB flux confined to the center of the rings, that is, $\ell = 0$. We summarize our conclusions in Section “Conclusion”.

Radial potential

The confinement of electrons in a limited region of the surface is described by a radial potential (Tan and Inkson, 1996), given by

$$V(r) = \frac{a_1}{r^2} + a_2 r^2 - V_0, \quad (1)$$

with $V_0 = 2\sqrt{a_1 a_2}$. This radial potential has a minimum at $r_0 = (a_1/a_2)^{1/4}$. If $r \approx r_0$, we obtain the parabolic potential model,

$$V_{par}(r) \approx \frac{\mu\omega_0^2}{2}(r - r_0)^2, \quad (2)$$

Fig. 1 In (A), the radial potential describes a narrow ring by $\hbar\omega_0 = 460$ meV, while in (B), the radial potential describes a wide ring defined by $\hbar\omega_0 = 50$ meV. The radius of both rings is $r_0 = 10$ nm.

where $\omega_0 = \sqrt{8a_2/\mu}$ characterizes the strength of the transverse confinement. Both the radius and the width of the ring can be adjusted independently by suitably choosing a_1 and a_2 . Alternatively, we can use the effective radius of the ring r_0 and the characteristic frequency of the radial confinement ω_0 . In particular limits, the potential (1) can describe a quantum dot, a quantum anti-dot, a two-dimensional wire, or even a 1D ring (Tan and Inkson, 1996).

Fig. 1 shows the radial potential, given by Eq. (1), for rings of different widths. In Fig. 1A, the radial potential describes a narrow ring with $r_0 = 10$ nm and $\hbar\omega_0 = 460$ meV. In Fig. 1B, the radial potential describes a wide ring with $r_0 = 10$ nm and $\hbar\omega_0 = 50$ meV. Both the samples are made of GaAs, so the electron effective mass is $\mu = 0.067\mu_e$, where μ_e is the electron mass.

Description of the model

The description of the model of a particle constrained to move on a curved surface by the action of an external potential was given by da Costa (1981). Using a thin-layer quantization procedure, it was shown that the transverse and the surface motion are exactly separable. Ferrari and Cuoghi (2008) generalized this result, and showed that using both the thin-layer quantization procedure and a proper choice of the gauge, the transverse and motion on the surface of the charged particle in the presence of external electric and magnetic fields are also decoupled. Such equations are found to be

$$i\hbar \frac{\partial}{\partial t} \chi_N = -\frac{\hbar^2}{2M} \partial_3^2 \chi_N + V_\lambda(q_3) \chi_N, \quad (3)$$

and

$$i\hbar \frac{\partial}{\partial t} \chi_S = \frac{1}{2\mu} \left[-\frac{\hbar^2}{\sqrt{g}} \partial_a (\sqrt{g} g^{ab} \partial_b) + \frac{ie\hbar}{\sqrt{g}} \partial_a (\sqrt{g} g^{ab} A_b) + 2ie\hbar g^{ab} A_a \partial_b + e^2 g^{ab} A_a A_b + V_g + eU \right] \chi_S, \quad (4)$$

where e is the charge of the particle, μ is the effective mass and $a, b = 1, 2$. In the equation that governs the motion in the transversal direction (Eq. 3), we have just the external potential V_λ , which confines the particle on the surface (da Costa, 1981). On the other hand, in the equation that governs the dynamics on the surface (4), we have the scalar potential U and the vector potential A_i . In addition, a curvature-induced potential V_g appears in the equation that describes the dynamics on the surface, which is given by

$$V_g = -\frac{\hbar^2}{2\mu} (\mathcal{H}^2 - \mathcal{K}), \quad (5)$$

where $\mathcal{H}$ and $\mathcal{K}$ are mean and Gaussian curvatures, respectively. In our study, we are interested only in the motion on the surface without the presence of the external electric field.

Let us consider the line element in polar coordinates (Filgueiras and Moraes, 2008; Filgueiras et al., 2012),

$$ds^2 = dr^2 + \alpha^2 r^2 d\varphi^2, \quad (6)$$

where $r \geq 0$ and $0 \leq \varphi < 2\pi$. The α parameter defines the type of surface that the metric (6) describes. If $0 < \alpha < 1$ (deficit angle), the metric describes a conical surface while $\alpha > 1$ (proficit angle), the metric defines a saddle-like surface. If $\alpha = 1$, then we recover the flat surface. Here, we focus our analysis in the range $0 < \alpha \leq 1$. The Gaussian and the mean curvatures are given, respectively, by Carvalho et al. (2007)

$$\mathcal{K} = \left(\frac{1-\alpha}{\alpha}\right) \frac{\delta(r)}{r}, \quad \mathcal{H} = \frac{\sqrt{1-\alpha^2}}{2\alpha r}. \quad (7)$$

The corresponding geometric potential (5) is written as

$$V_g(r) = -\frac{\hbar^2}{2\mu} \left[\frac{1-\alpha^2}{4\alpha^2 r^2} - \left(\frac{1-\alpha}{\alpha}\right) \frac{\delta(r)}{r} \right], \quad (8)$$

with μ being the electron effective mass and the $\delta(r)$ function describes a singularity at $r = 0$ region. Note that the Gaussian curvature is associated with the singularity at the cone apex.

The vector potential is chosen to be

$$\mathbf{A} = \frac{Br}{2\alpha} \hat{\varphi} + \frac{\ell\hbar}{e\alpha r} \hat{\varphi}, \quad (9)$$

where $\ell = \Phi_{AB}/\Phi_0$ is the AB flux parameter and $\Phi_0 = h/e$ is the magnetic flux quantum. The vector potential (9) implies a superposition of magnetic fields (a uniform magnetic field plus a magnetic flux tube) given by

$$\mathbf{B} = B \hat{\mathbf{z}} + \frac{\ell\hbar}{e\alpha r} \delta(r) \hat{\mathbf{z}}. \quad (10)$$

By using Eqs. (1), (8), (9), and (10) in Eq. (4), we write

$$E\chi_S(r, \varphi) = \left\{ -\frac{\hbar^2}{2\mu} \left[\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial}{\partial r} \right) + \frac{1}{\alpha^2 r^2} \left(\frac{\partial}{\partial \varphi} - i\ell \right)^2 \right] - \frac{\hbar^2}{2\mu} \left[\frac{ieB}{\hbar\alpha^2} \left(\frac{\partial}{\partial \varphi} - i\ell \right) + \frac{e^2 B^2 r^2}{4\hbar^2 \alpha^2} \right] \right. \\ \left. - \frac{\hbar^2}{2\mu} \left[\frac{(1-\alpha^2)}{4\alpha^2 r^2} - \left(\frac{1-\alpha}{\alpha}\right) \frac{\delta(r)}{r} \right] + \frac{a_1}{r^2} + a_2 r^2 - V_0 \right\} \chi_S(r, \varphi). \quad (11)$$

By considering solutions of the form

$$\chi_S(r, \varphi) = e^{im\varphi} f_m(r), \text{ with } m = 0, \pm 1, \pm 2, \dots \quad (12)$$

Eq. (11) provides us the following radial differential equation for a specific quantum number m :

$$-\frac{\hbar^2}{2\mu} \frac{1}{r} \frac{d}{dr} \left(r \frac{d}{dr} \right) f_m(r) + V_{\text{eff}} f_m(r) = E_m f_m(r), \quad (13)$$

where

$$V_{\text{eff}} = \frac{\hbar^2}{2\mu} \left(\frac{L^2}{r^2} + \frac{r^2}{4\lambda^4} - \kappa^2 \right) + \frac{\hbar^2}{2\mu} \left(\frac{1-\alpha}{\alpha} \right) \frac{\delta(r)}{r} \quad (14)$$

is the induced effective potential. We define the effective angular momentum, the effective cyclotron frequency, the effective magnetic length, and a constant parameter, respectively, as

$$L = \sqrt{\left(\frac{m-\ell}{\alpha}\right)^2 + \frac{2\mu a_1}{\hbar^2} - \frac{1-\alpha^2}{4\alpha^2}}, \quad (15)$$

$$\omega = \sqrt{\left(\frac{\omega_c}{\alpha}\right)^2 + \omega_0^2}, \quad (16)$$

$$\lambda = \sqrt{\frac{\hbar}{\mu\omega}}, \quad (17)$$

$$\kappa^2 = \frac{(m-\ell)\mu\omega_c}{\hbar\alpha^2} + \frac{2\mu V_0}{\hbar^2}, \quad (18)$$

where $\omega_c = eB/\mu$ is the cyclotron frequency. It is important to emphasize that the presence of the δ function in Eq. (13), which is a short-range potential, suggests that those singular solutions should be taken into account in this approach. According to von Newman's theory of self-adjoint extensions (Reed and Simon, 1975), the necessity of inclusion of the irregular solutions of Eq. (13) stems from the fact that H (Eq. 11) is not self-adjoint for $|L| < 1$ (Andrade et al., 2012, 2013). However, as the effective angular moment (15) is larger than 1, there is no value of L belonging to the range required above. Because of this, we can ignore the δ function in the radial equation (14) and consider only the regular solution at $r = 0$. In this manner, the energy eigenvalues and wavefunctions of Eq. (11) are given by

$$E_{n,m} = \left(n + \frac{1}{2} + \frac{L}{2} \right) \hbar\omega - \frac{(m-\ell)\hbar\omega_c}{2\alpha^2} - V_0, \quad (19)$$

$$\chi_{n,m}(r, \varphi) = \frac{1}{\lambda} \sqrt{\frac{\Gamma(L+n+1)}{2^L n! \Gamma(L+1)^2}} e^{-\frac{r^2}{4\lambda^2}} e^{im\varphi} \left(\frac{r}{\lambda}\right)^L {}_1F_1\left(-n, 1+L, \frac{r^2}{2\lambda^2}\right). \quad (20)$$

Another relevant quantity in this model is the effective radius $r_{n,m}$ of the states with quantum number m is

$$r_{n,m} = (2L)^{\frac{1}{2}} \lambda, \quad (21)$$

where L and λ are given by (15) and (17), respectively.

Electronic states

In this section, we analyze the energy spectrum of the 2D quantum ring (19). Using Eq. (19), we can see that both states with $m > 0$ and $m < 0$ have the same energy. This double degeneracy is due to the rotational symmetry present in the ring. The quantum states in different subbands do not have the same symmetry due to the antidot potential (Eq. 1). The separation energy between adjacent subbands is equal to $\hbar\omega_0$. All the information described above remains valid for $\alpha < 1$, but now we have larger energies, except the state with $m = 0$, as a consequence of the presence of the geometric potential, as can be seen by replacing $m = 0$ in Eq. (19). Therefore, for a given Fermi energy E_F , the number of states with energy $E_{n,m} \leq E_F$ decreases when the α parameter decreases. For the physical phenomena that we will deal with in the next sections, the number of electrons in the system is fixed. Thus, we will observe the increase of the Fermi energy in this case. In addition, if there are a large number of electrons in the ring, the curvature also tends to increase the number of occupied subbands (Pereira et al., 2019, 2021).

In the presence of a magnetic field, Eq. (19) shows that the energy spacing between the adjacent subbands is now given by $\hbar\omega$ and it increases as the magnetic field is raised. The curvature enhances such an effect, as shown in Eq. (16). By using Eq. (19), we can show that for a specified magnetic field value, all the minimums of the subbands lie at the same state with $m = m_0$, given by

$$m_0 = \frac{eBr_0^2}{2\hbar} \sqrt{1 - \frac{1}{a_1} \frac{\hbar^2}{2\mu} \frac{1 - \alpha^2}{4\alpha^2}}. \quad (22)$$

For $\alpha = 1$, we recover the result obtained by Tan and Inkson (1996), which corresponds to the number of quantum flux threading a ring with an effective radius r_0 , that is, $m_0 = \Phi/\Phi_0$, where $\Phi = \pi r_0^2 B$. For a null magnetic field, all the subband minima are the $m_0 = 0$ state. Eq. (22) shows that the minimum of all subbands changes with the variation of the magnetic field.

The purpose of this work is to analyze the effect of curvature in narrow and wide rings. From now on, in numerical analyses, we consider the rings narrow and wide presented in Fig. 1A and B, respectively.

Fig. 2 shows the behavior of the energy levels of the narrow ring with respect to the magnetic field for some values of the α parameter. As expected, in Fig. 2A, which describes the case without curvature, the evolution of the energy levels is close to that of a 1D ring. The spectrum consists of parabolas shifted with respect to each other. In other words, the condition for periodicity of the spectrum (Avishai et al., 1993; Ihn et al., 2003)

$$E_{n,m}\left(m, \frac{\Phi}{\Phi_0} + 1\right) = E_{n,m}\left(m+1, \frac{\Phi}{\Phi_0}\right) \quad (23)$$

is approximately satisfied in the magnetic field range under study. Fig. 2B and C shows the behavior of the energy levels when the parameter α takes the values 0.8 and 0.7, respectively. We can assume that the condition for the periodicity of the spectrum is still valid. On the other hand, for $\alpha = 0.5$, which corresponds to Fig. 2D, we can see an evident deviation from the condition for the periodicity of the spectrum for $B > 2$ Teslas. Therefore, we conclude that the curvature enhances the effect of the magnetic field at the subband minimum. Namely, in this work, the condition for periodicity of the spectrum (Eq. 23) is related to the narrow ring limit, that is, $\alpha^{-1}\omega_c \ll \omega_0$. In higher subbands, there is also a break of periodicity to lower magnetic fields since the separation energy

Fig. 2 The energy levels of a narrow ring, calculated without (A) and with (B–D) curvature, as a function of the magnetic field.

Fig. 3 The energy levels of a wide ring, calculated without (A) and with (B–D) curvature, as a function of the magnetic field.

Fig. 4 The energy levels of a narrow ring (panel (A)) and wide ring (panel (B)) as a function of the α parameter for $B = 0$.

between adjacent subbands increases with the increasing magnetic field. Furthermore, we verify that the density of states decreases with increasing curvature. This result shows that the role of curvature, in general, is to shift the energy spectrum to higher values of energy.

Fig. 3, shows the behavior of the energy levels of the wide ring with respect to the magnetic field for some values of the α parameter. The energy spectrum is very different from the case of a narrow ring (see Fig. 2), which demonstrates the effect of electrostatic confinement energy $\hbar\omega_0$. In a ring with a finite width, the penetration of the uniform magnetic field into the conducting region of a ring also plays an important role (Tan and Inkson, 1996). It is clear from the discussion above that the effect of curvature is much more pronounced, as we can see in Fig. 3B–D. The behavior of energy levels is now quite complex, especially when there is more than one subband occupied. It is clear that the only effect of the geometric potential is to shift the state with $m = 0$ to lower values of energy, as shown in Fig. 4A and B, which describe, the behavior of energy levels as a function of α parameter when $B = 0$. It is interesting to note that the influence of the geometric potential is very sensitive to the geometry of the device (Pereira et al., 2021). In fact, in the limit where $r_0 = 0$, which describes a quantum dot, the state with $m = 0$ is not a physical state (Pereira et al., 2019). In the wide ring, we can see that the curvature induces energy-level crossings. This occurs because the curvature effect is more pronounced in higher states in a subband. In addition, there is the effect of the geometric potential in states with $m = 0$, as already discussed.

Magnetization

The magnetization is given by

$$M = -\frac{\partial F}{\partial B} = -\sum_{n,m} M_{n,m} f_F(E_{n,m}), \quad (24)$$

where F is the free energy, $M_{n,m} \equiv -\partial E_{n,m}/\partial B$ defines the magnetic moment, and $f_F(E_{n,m})$ is the Fermi distribution function. By using Eq. (19), the magnetic moment is written explicitly as

$$M_{n,m} = -\frac{\hbar e}{\mu\alpha^2} \left[\left(n + \frac{1}{2} + \frac{L}{2} \right) \frac{\omega_c}{\omega} - \frac{m-l}{2} \right]. \quad (25)$$

Fig. 5 presents the behavior of magnetization over a wide range of magnetic fields for the narrow ring. In Fig. 5B–D, the dashed lines, that correspond to the case $\alpha = 1$, allow observing the differences between the models with and without curvature. The oscillations are AB type, which arise from the states crossing in Fermi energy. In a narrow ring, not strictly 1D, the magnetization

Fig. 5 Magnetization of a narrow ring, calculated without (A) and with (B–D) curvature, as a function of the magnetic field. The *dashed lines* in B–D correspond to the case without curvature $\alpha = 1.0$. Temperature removes the discontinuities of AB oscillations and decreases the oscillation amplitude.

Fig. 6 Magnetization of a wide ring, calculated without (A) and with (B–D) curvature, as a function of the magnetic field. The *dashed lines* in B–D correspond to the case without curvature $\alpha = 1.0$. Temperature removes the discontinuities of AB oscillations and decreases the oscillation amplitude.

presents oscillations almost perfectly sawtoothlike. For $\alpha < 1$, Fig. 5B–D, we observe that there is an increase in the amplitude of the AB oscillations. This occurs due to an increase in the rate of change of energy levels with the magnetic field, as shown in Fig. 2B–D. The oscillations, almost sawtoothlike, are still visible. Nevertheless, for $\alpha = 0.5$, the combined effect of the magnetic field with the curvature shows a small damping of the oscillations. This result is in agreement with the one discussed in Fig. 3D, in which the effect of the magnetic field at the bottom of the first subband is quite pronounced due to the curvature. Fig. 5D also shows a smooth phase shift between the without curvature and the with curvature system.

Fig. 6 shows the behavior of the magnetization of a wide ring as a function of the magnetic field. In Fig. 6B–D, the *dashed lines*, that correspond to the case $\alpha = 1$, allow observing the differences between the models with and without curvature. As observed in Fig. 3, the energy spectrum of the wide ring is aperiodic as a function of the magnetic field. As a consequence, we can see that the

amplitude of the oscillations decreases significantly as the magnetic field increases. In addition, we see a shift of the oscillations toward larger negative values when the magnetic field increases. As already reported, the curvature increases the effect of the magnetic field, as shown in Fig. 6B–D. Indeed, we can show that the magnetization tends to the value $-NM_0/\alpha^2$ when $B \rightarrow \infty$, where $M_0 = e\hbar/2\mu$ is the effective Bohr magneton. When comparing with Fig. 5, the role of confinement in the physical properties of the ring is evident. It is interesting to note the increase in the number of aperiodic oscillations at low values of the magnetic field for $\alpha = 0.5$, as we can see in Fig. 6D. Indeed, as we can discuss in Fig. 4, the effect of curvature on states is not uniform. In a curved semiconductor ring with 5 electrons, some electrons occupy a few states in the second subband, in particular, the state with $m = 0$. More electron-level crossings lead to a more complicated oscillating structure of magnetization as a function of the magnetic field as compared to the case when $\alpha > 0.5$.

In addition, Fig. 6D shows that for $\alpha = 0.5$, the magnetization presents an initial phase opposite to the cases shown in Fig. 6A–C. As shown in Fig. 3B, a crossing of degenerate levels $(0, \pm 2)$ with level $(1, 0)$ occurs at $\alpha \approx 0.63$, and the ground state configuration of the wide ring changes. Therefore, the opposing phases are not necessarily related to the even or odd number of electrons in the ring (Chakraborty and Pietiläinen, 1994). Here, opposite phases are attributed to the curvature.

The effect of temperature on the magnetization in narrow and wide rings is shown in Figs. 5 and 6, respectively. With increasing temperature, the oscillations acquire smooth behavior and decrease in magnitude. However, this effect is less pronounced when the α parameter takes on values lower. Indeed, there is an increase in energy-level spacing and, consequently, less contribution from the lower states.

Persistent current

By considering the variation of the magnetic flux confined to the hole of the ring, the persistent current is calculated using the Byers–Yang relation (Byers and Yang, 1961)

$$I_{n,m} = -\frac{\partial E_{n,m}}{\partial \Phi_{AB}} = -\frac{1}{\Phi_0} \frac{\partial E_{n,m}}{\partial \ell} \quad (26)$$

where $E_{n,m}$ is then given by Eq. (19). The total current is given by

$$I = \sum_{n,m} I_{n,m} f_F(E_{n,m}), \quad (27)$$

where $I_{n,m}$ is explicitly given by

$$I_{n,m} = \frac{e\omega}{4\pi\alpha^2} \left(\frac{m-\ell}{L} - \frac{\omega_c}{\omega} \right), \quad (28)$$

which is the persistent current carried by a given state $\chi_{n,m}$ of the ring.

As noted by Tan and Inkson (1999), the proportionality between the current and the magnetic moment observed in a one-dimensional ring is broken in a two-dimensional ring as a result of the penetration of the magnetic field into the conducting region of the ring. In the presence of curvature, this relation between the current and the magnetic moment is given by

$$M_{n,m} = \pi r_{n,m}^2 I_{n,m} - \frac{e\hbar}{\mu\alpha^2} \left(n + \frac{1}{2} \right) \frac{\omega_c}{\omega}. \quad (29)$$

The first term is the current in a one-dimensional ring with radius $r_{n,m}$ given by Eq. (21). The second term results from the penetration of the magnetic field into the 2D structure, being it a diamagnetic term. From this result, it is possible to show that if $\omega_c \ll \omega_0$ the persistent current and the magnetization present similar behavior.

Fig. 7 shows the persistent current in a narrow ring as a function of the magnetic field. We emphasize that the narrow ring model has a finite width, that is, it is not strictly a 1D ring. Thus, although oscillations sawtoothlike are observed, it is evident that diamagnetic term breaks the proportionality between the magnetic moment and the persistent current, as we can observe by comparing Fig. 5 with Fig. 7. In a wide ring, the effect of the magnetic field on the conducting region is more evident. Indeed, comparing Fig 6 with Fig. 8, we see that magnetization and persistent current have very different behavior.

Conclusion

In this article, we studied the electronic properties, the magnetization, and the persistent current of a 2DEG in narrow and wide rings in a conical metric and submitted to an external magnetic field. We have obtained analytically the wave functions and energy eigenvalues. It was shown that the curvature has a strong influence on the spectrum of an electron in quantum rings. This was verified by observing that the energy of the states is increased; the effects become more significant as the α parameter decreases. In particular, the size of the device, which is determined by the radius r_0 and transverse confinement ω_0 , plays a crucial role in analyzing effects due to the geometric potential (see Fig. 4A and B). In other words, the influence of the mean curvature on the energies is limited by the value of the parameter a_1 . This shows that the influence of the geometric potential is very sensitive to the geometry of the device. For the particular case of $r_0 = 0$, which corresponds to $a_1 = 0$, the mean curvature directly influences the behavior of the electronic states in a quantum dot (Pereira et al., 2019). These results have consequences on the occupation of the

Fig. 7 Persistent current (in units of $I_0 = e\hbar/2\mu\pi r_0^2$) of a narrow ring, calculated without (A) and with (B–D) curvature, as a function of the magnetic field. The dashed lines in B–D correspond to the case without curvature $\alpha = 1.0$. Temperature removes the discontinuities of AB oscillations and decreases the oscillation amplitude.

Fig. 8 Persistent current (in units of $I_0 = e\hbar/2\mu\pi r_0^2$) of a wide ring, calculated without (A) and with (B–D) curvature, as a function of the magnetic field. The dashed lines in B–D correspond to the case without curvature $\alpha = 1.0$. Temperature removes the discontinuities of AB oscillations and decreases the oscillation amplitude.

states in the Fermi energy, and consequently on the behavior of magnetization and persistent current. For instance, an increase in the amplitude of type-AB oscillations was noted in magnetization and persistent current. In addition, for $\alpha = 0.5$, we saw a complex pattern of AB-type oscillation in magnetization and persistent current in a wide narrow. It is evident that the low electron occupancy in quantum rings also contributes to a significant geometric potential effect on physical properties. We also investigated the effects of temperature on the physical properties of the mesoscopic ring. Figs. 5–8 showed that the amplitude of the oscillations decreases. The physical properties of mesoscopic systems are directly dependent on the temperature, which is a known result in the literature.

In the context of real physical models, the method proposed by Lorke et al. (2003) provides a possible experimental verification for the model studied in this work. In it, the authors introduced a method that allows one to lift off thin films of patterns containing a high-mobility 2DEG. Because of the flexibility of the thin film, it is then possible to transfer the heterostructure onto a cylindrical

substrate and thus access the mesoscopic properties of an electron gas on a curved sample. Here, we would have a cone instead of a cylinder. This would set up a ribbon on the surface of a cone. Usual techniques could then be used to measure the persistent current. One way is to detect the magnetic field generated by the current loop by using a superconductive quantum interference device (SQUID) (Heinzel, 2006; Mailly et al., 1993).

Abstract

We discuss the mechanisms of the transformation of InAs Quantum Dots into Quantum Rings (QRs) using a partial capping technique. We demonstrate the presence of a large fraction of stress-induced liquid indium that plays a fundamental role in the growth of nanostructures. The presence of liquid indium enables a de-wetting process that produces a “nano-eruption” creating Quantum Rings. A diffusive indium-gallium exchange and intermixing form alloyed InGaAs regions, what prevents further stress-induced melt. The competition between de-wetting and intermixing determines the final shape and size of these self-assembled nanostructures. Quantum Rings (QRs) are defect-free, coherent nanostructures that show an Aharonov-Bohm effect. They are excellent candidates to be used as crucial active elements for various quantum applications.

Key points

- Mechanism of Quantum Rings formation discussed
- Experimental demonstration of a stress-free indium at the surface during the deposition of InAs on GaAs(001) over a large range of substrate temperature
- Size and shape control of ensembles of Quantum Dots using partial capping technique
- Aharonov-Bohm effect demonstrated in Quantum Rings

Introduction

Semiconductor materials have contributed to the establishment of the modern current society as we know it. The majority of applications use silicon as the basic material in which the processors and devices are built. But there are many applications, mainly those in which optoelectronics are involved, in which other semiconductors based on III–V materials are crucial. These later materials are very important not only for well established technologies as lasers, LED, detectors, IR-detectors, concentration solar cells, power electronics; but they are expected to become the core elements for next generation of solid-state quantum computers, that could deliver the second quantum revolution in the coming decades (Dowling and Millburn, 2003; Gurioli et al., 2019). As an example, the possibility of fabrication of a single photon emitter (Michler et al., 2000) was early demonstrated. Furthermore, electrically driven and tunable plug-&-play single photon sources are being developed (Alen et al., 2019; Fuster et al., 2020).

The use of self-assembled Quantum Dot (QDs) structures fabricated on GaAs by Molecular Beam Epitaxy (MBE) and other growth techniques, is a mature technology in order to achieve this purpose. It is crucial the possibility of controlling and tuning the interaction of photons and electrons. Photonic structures provide a way of tuning the wavelength properties.

One of the most common materials systems of QDs is the use of InAs on GaAs. Since pioneering works that discovered the formation of InAs QDs in the early 1990s (Brandt et al., 1991; Leonard et al., 1993), QDs have become a central topic in nanoscience and nanotechnology. Solid pseudomorphic InAs on GaAs(001) has a -6.7% strain. This mismatch builds up a large strain energy (accumulation of stress) during the growth of InAs on GaAs, that results in the formation of self-assembled nanostructures on the surface of GaAs that help relax such elastic energy. When these lens-shaped nanostructures are capped in

[☆]Change History: August 2022. JM García updated the chapter.

an embedding GaAs matrix they confine carriers in three dimensions behaving like artificial atoms. In order to achieve accurate control of the electronic properties of these nanostructures it is required mastering the growing processes that takes place during formation and during capping. The use of techniques capable to create uniform ensembles of QDs, controlling not only the density but also their size is important.

The process of capping an ensemble of QDs is a dynamical competition between quenching its size and shape with other processes like de-wetting, segregation and alloying that drastically modify the original uncapped dots. It is possible to achieve extra control on the final confining properties by using a partial capping technique (Garcia et al., 1997). Recently, similar effects have been used to radically modify the shape of QDs to produce wetting-layer-free QDs (Löbl et al., 2019). These new QDs are excellent candidates to be used in solid-state quantum information processing devices. When the QDs are partially covered, a growth pause induces a reduction of the vertical size of the nanostructures (Garcia et al., 1998). It was early demonstrated that this growth pause allowed tuning, not only of the size, but also the shape; leading to the fabrication of Quantum Rings (QRs) (Garcia et al., 1997, 2014). Further work demonstrated that they behave like the “smallest rings of electricity” (Lorke, 2000).

The unique ring-like density of states of Quantum Rings for charge carriers, spins, plasmon and photon fields provide a rich wealth of fascinating properties and possibilities to develop strategic areas of next future technology: quantum computing based on photon and spin manipulations, photonic sources and detectors, magnetic memory, and functionalization of nanostructured metamaterials (Fomin, 2018b).

Seminal early work on other type of QRs was performed showing evidence for a flux periodic persistent current in rings made of various materials such as: copper (Lévy et al., 1990), gold (Chandrasekhar et al., 1991), GaAs-AlGaAs (Mailly et al., 1993) or AlSb/InAs/AlSb (Morpurgo et al., 1998). In all these mesoscopic structures scattering effects from fabrication defects were present inhibiting their true quantum limit behavior.

The Quantum Rings explored in this Chapter are a particular case of defect-free self-assembled nanostructures. They are fabricated by means of Molecular Beam Epitaxy. They were first developed in a pioneering work by Axel Lorke and Jorge M. García in 1997 in the group of Pierre M. Petroff in a successful collaboration that took place at the University of California Santa Barbara (UCSB), USA. During many years, the appropriate growing conditions that were used for their fabrication stayed unwillingly hindered within the secrets of the particular experimental growth reactor that was used. As a result of the research studies on the mechanism of QDs transformation into QRs that Daniel Granados performed in his PhD works at the Instituto de Micro and Nanotechnology-CSIC (in those days named Instituto de Microelectronic of Madrid), finally in 2003 the “secrets” of ring formation were unveiled. Further work focusing on the accumulated stress evolution during heteroepitaxial growth of mismatched layer, greatly contributed to the understanding of QR formation.

A few years after the report of the growth of ring-shaped nanostructures in 1997 (Garcia et al., 1997) it was demonstrated that these new types of self-assembled nanostructures were truly Quantum Rings, i.e., they were defect-free, coherent nanostructures, achieving the Heisenberg true quantum limit (Lorke, 2000; Lei and Lorke, 2014). They show characteristic and unique properties of QRs, which can be observed with the presently available magnetic fields. For example, in 2007 Kleemans et al. demonstrated by means of magnetization experiments, using a torque magnetometer, the presence of the persistent current carried by a single electron showing an Aharonov-Bohm (Aharonov and Bohm, 1959) effect. The first oscillation was observed at the magnetic field of 14 T in a sample grown with 29 layers of stacked self-assembled Quantum Rings sample, in perfect agreement with the theoretical model based on the structural properties determined by cross-sectional scanning tunneling microscopy measurements (Kleemans et al., 2007). These developments opened a vast field of research devoted to the physics of Quantum Rings (Fomin, 2014, 2018a).

There are other material systems in which defect-free self-assembled Quantum Rings have been developed, including: InAs on InP (Raz et al., 2003), the use of partial capping with AlAs (Lee and Lee, 2004), GaSb/GaAs (Kobayashi et al., 2004), droplet epitaxy (Mano et al., 2009; Heyn et al., 2011; Wu and Wang, 2014, 2018; Sanguinetti et al., 2014), GeSi ring structures from germanium dots partially capped with silicon (Cui et al., 2003).

We discuss the mechanisms of the transformation of QDs into QRs using a partial capping technique. We demonstrate the presence of a large fraction of stress-induced liquid indium that plays a fundamental role in the growth of nanostructures. The presence of liquid indium enables a de-wetting process that produces a “nano-eruption” creating nanovolcanoes, that can be truthfully called Quantum Rings. A diffusive indium-gallium exchange and intermixing form alloyed InGaAs regions, what prevents further stress-induced melt. The competition between de-wetting and intermixing determines the final shape and size of these self-assembled nanostructures. We show how to control and use these processes to tailor size and shape of nanostructures.

Growth of InAs on GaAs. Wetting layer, quantum dots and quantum rings

We review the formation of InAs nanostructures taking into account the conclusions obtained from measurements of the accumulated stress during nanostructure formation. First, we will show that during the growth of one monolayer of InAs, apparently the simplest case, the presence of liquid indium on the surface is experimentally confirmed. This understanding will later help explain the formation of Quantum Dots and Quantum Rings.

Experimental details: MBE with in-situ characterization

The MBE at IMN has several in-situ characterization techniques that make of it a unique system. It has Reflection High Energy Electron Diffraction (RHEED), Reflectance Difference (RD) and accumulated stress measurements ($\Sigma\sigma$). $\Sigma\sigma$ is acquired by measuring the radius of curvature of a thin lever-shaped sample with two laser beams impinging perpendicularly to the sample (Fig. 1).

Fig. 1 Experimental set up for in-situ accumulated stress ($\Sigma\sigma$) measurements. A cantilever-shaped GaAs substrate is clamped in one side letting it freely bend under the accumulation of stress due to heteroepitaxial growth. Changes in $\Sigma\sigma$ are calculated using Stoney's equation by measuring the radius of curvature with two parallel laser beams. The surface reconstruction (monitored using RHEED) is used to have a precise control of the temperature of the substrate.

The sample is clamped to the sample holder in one side (see inset Fig. 1) and can freely bend induced by the accumulation of stress during the growth of mismatched materials, thanks to an opening in the substrate holder. The changes in $\Sigma\sigma$ are calculated using Stoney's equation (Freund et al., 1999; Garcia et al., 2000). A red laser beam is split into two parallel laser beams with a beam splitter. The detection of the reflected beams is made with a split photodiode or with a CCD camera. All the optics are placed outside the MBE chamber and only require an optical heated viewport placed in front of the substrate. The growth takes place on GaAs(001) samples which are cut from 100 to 150 μm -thick wafers. They are lever-shaped with the larger dimension along either [110] or $[1\bar{1}0]$ to explore the two principal crystallographic directions. During growth of InAs on GaAs, the substrate temperature is carefully calibrated and set using the RHEED patterns, since the opening in this special substrate holder makes the reading in the thermocouple completely different than when a regular holder is used.

Wetting layer. Presence of stress-induced melted indium

One of the simplest heteroepitaxial growth experiment of lattice mismatched materials is the growth of one monolayer (ML) of InAs on GaAs, commonly named wetting layer (WL). Initial stages of submonolayer InAs epitaxy on GaAs (Bressler-Hill, 1994) showed anisotropic nucleation effects, suggesting strain effects to be responsible for these observations. It is well known that 1 ML of InAs is providing not enough accumulated stress to induce a 3D roughening transition. It is commonly assumed that InAs grows lattice matched to GaAs for the first monolayer. For this reason, it is commonly called wetting layer.

It was assumed (and still is nowadays) that only later during capping of this layer there was atomic segregation (Kawai et al., 1993), surface exchange between column-III atoms (Moison et al., 1989), and other processes that are responsible for the well-known problem of formation of no sharp interface which make unrealistic the assumption of abrupt potential well confinement for carriers. This is not the case, as it is demonstrated by the results of measuring the accumulated stress during growth of 1 ML of InAs on GaAs and further capping with GaAs with an Arsenic beam equivalent pressure of 2.2×10^{-6} Torr (2.93×10^{-4} Pa) at 414 °C (see Fig. 2).

The accumulated stress increases as soon as the growth of the heteroepitaxial layer begins (green trace), then, during a 30 s growth pause under arsenic, the stress stays stable (black trace), but during capping with GaAs, an unexpected further increase on the accumulated stress is observed (red trace). Isotropic results are obtained in both principal crystallographic directions [110] and $[1\bar{1}0]$, as expected from a InAs, As-terminated layer. If all the InAs were pseudomorphically incorporated into the GaAs substrate, and therefore 2D compressed, no such further increase in accumulated stress would be measured. Such behavior shines new light into the understanding of the growth on InAs on GaAs. From the ratio of the increase in $\Sigma\sigma$ during InAs deposition and during further capping, we can estimate that at this temperature only about 65% of the InAs layer is in a solid state fully stressed layer, the rest is in a fully relaxed stress-free state. So, there is a very large fraction (approx. 35%) of liquid InAs that is progressively incorporated into the GaAs matrix (see insert to Fig. 2C) during capping that induces another 1.4 N/m accumulation of stress. With this technique we can also measure in-situ and in real time the segregation length (W) of InAs with subatomic precision.

The results shown in Fig. 2 demonstrate that there is a large fraction on the supplied Indium that is in a stress-free state. Based on thermodynamical calculations of Gibbs free energy (Bottomley, 2002) it can be assumed that this material is in a liquid state which has been stress-induced melted.

Fig. 2 (A) Measurement of accumulated stress during deposition of 1 ML of InAs (green trace), growth pause (black trace) and further capping with GaAs (red trace) on GaAs(100). (B) This insert shows a cross section scheme during deposition of InAs on GaAs. A submonolayer InAs island is fully 2D compressed but is coexisting with a large fraction of fully relaxed Indium. (C) this scheme shows a cross section of how liquid Indium is progressively incorporated pseudomorphically during capping creating a graded top interface characterized by a segregation length (W). Berlin-Heidelberg: Springer.

Fig. 3 Accumulated stress measurements during growth of one monolayer of InAs on GaAs at various substrate temperatures. The horizontal dotted lines are a guide to the eye showing the mean value of the measurements of 1 ML and the total increase in accumulated stress after fully covered with GaAs. It is also plotted in hatched bar graphs the accumulated stress measurements during quantum dot formation and further capping (to be discussed later in the next section). After Silveira J, Garcia JM, and Briones F (2001) Surface stress effects during MBE growth of III-V semiconductor nanostructures. *Journal of Crystal Growth* 227–228: 995–999.

This fact was theoretically predicted (Bottomley, 2000) almost at the same time that it was proved experimentally (Garcia et al., 2000). This stress-free liquid indium is present for the whole range of substrate temperatures employed in MBE growth. In this chapter, the substrate temperature during growth is expressed in degrees Celsius ($^{\circ}\text{C}$), a unit commonly used in MBE. We have observed the same step-like behavior in the accumulation of stress during a wetting layer (1ML) growth and further cap from 170°C to 520°C (Silveira et al., 2001). In Fig. 3 we plot a bar graph representing the increase in $\Sigma\sigma$ during deposition of one monolayer of InAs at various temperatures (blue) which induced approximately 1.15 N/m . In some selected results we plot also the further increase of $\Sigma\sigma$ during capping (red). The total induced stress for a monolayer after capping is 2.15 N/m , close to a theoretical estimation of 1.7 N/m (Bottomley, 2002). Although a slight temperature dependance can be observed in the uncapped data, it is clear that there is always a further increase in $\Sigma\sigma$ during capping. The commonly known as wetting layer actually should be interpreted as an almost 50%:50% of wetting and “liquid” layer. There is always stress induced liquid indium during growth. This fact is key for understanding and controlling dot-to-ring re-assembly mechanisms.

Quantum dots

The fabrication of QDs that can be used for solid state device integration usually are obtained after embedding self-assembled islands into a larger band gap material, for example, InAs QD in a GaAs matrix layer. The island formation is a very fast process

Fig. 4 Accumulated stress evolution during quantum dot (QD) formation. After deposition of 1.7 ML of InAs ($\sim t = 56$ s), the formation of 3D islands is revealed in the appearance of a characteristic 3D RHEED pattern (insert A) and revealed by AFM exploration of uncapped samples (insert B). Since the onset of the 3D RHEED pattern at $t = 56$ s till the end of InAs deposition at $t = 66$ s the increase of accumulated stress is very small.

which usually is observed clearly as an almost instantaneous appearance of a 3D RHEED pattern (see insert to Fig. 4A). At this point, if the growth is stopped and the surface characterized by ex-situ AFM, the presence of self-assembled islands is revealed as can be observed in the insert to Fig. 4B.

In spite that the evaporation of InAs is still on after the formation of pseudomorphic, crystallographically-ordered 3D islands, the measured accumulated stress increases only slightly. This observation implies a large stress-induced migration and incorporation of a large amount of stress induced melted InAs available at the base of the QD toward the tip, building up taller dots.

From the conclusion of the previous section, it is important to remember that a large fraction (almost 50%) of stress-relaxed (liquid) indium is present on the GaAs interface at the onset of 3D island formation, therefore the island formation is a very complex process in which a large migration of indium (both liquid and the one which is arriving at the surface) toward the tip of the islands is expected. A very small increase in $\Sigma\sigma$ observed in Fig. 4, from $t = 56$ s to $t = 66$ s is in accordance with the stress-enhanced migration and incorporation of InAs at the tip of the dot, which is energetically favorable as the tip of these tall islands is largely relaxed (Kegel et al., 2000).

During the process of capping the islands, the same driving forces that are responsible for the formation of the islands, are present inducing a “self-disassembling” of the dots. When the dots are capped, there is an almost another 50% additional increase of $\Sigma\sigma$ (red and blue hatched bar graphs in Fig. 3), that reflects the progressive incorporation of large quantities of stress-free indium into the GaAs matrix.

All these processes are playing an important role during ring formation as will be discussed in the next section.

Formation and optical properties of Quantum Rings

We will focus on the growth of InAs QR on GaAs(100) by the partial capping technique (Garcia et al., 1997). The fabrication of self-assembled Quantum Rings (QRs) requires the use of a seed layer of self-assembled QDs.

It is crucial to use an ensemble of QD with the following properties: uniform size distribution (both vertically and in-plane), low area density ($\leq 1 \times 10^9$ QD $\times$ cm $^{-2}$), and with a mean value of the height of the dots larger than 7 nm. A low area density helps AFM characterization. The growth conditions for obtaining such QD ensemble (see Fig. 5A) is $T_{\text{substrate}} = 540$ °C, an As $_2$ beam equivalent pressure $\text{BEP}_{\text{As}} = 1.2 \times 10^{-6}$ Torr (1.6×10^{-4} Pa), details in reference (Granados and Garcia, 2003).

A growth pause, when the dots are partially capped, triggers the transformation of dots (Fig. 5A) into ring structures (see Fig. 5B). The dots are partially covered with 2 nm of GaAs at $T_{\text{substrate}} = 500$ °C (growth rate of 1ML/s), and then they are annealed at 500 °C for 60 s. As can be observed in the AFM profiles depicted in Fig. 6, there is a large reduction on the vertical size of the nanostructure, and an annular redistribution of material. We never obtained QRs for ensembles of QDs with vertical dimensions measured by AFM less than 7 nm. In order to achieve isotropic rings, we use a BEP of 1.5×10^{-6} Torr (2.0×10^{-4} Pa) As $_2$. It has been shown that the use of higher arsenic pressure promotes more isotropic growth along the principal direction [110] and $[1\bar{1}0]$ (Horikoshi et al., 1990). The use of As $_2$ has similar effects to employing a larger As $_4$ flux (Ogura et al., 2001).

The reduction in the vertical size observed in Fig. 6 has a strong influence in the vertical confining potential as can be observed in the low temperature photoluminescence spectra shown in Fig. 7. The transitions from the ground state E_0 can be observed at a moderately low laser pumping power of 20 mW. The emission E_0 is shifted 220 meV when an ensemble of QD (b) is compared to an ensemble of Quantum Rings (c). The WL peak can only be observed for the QR sample. The peak observed at 1.19 eV is the first excited state E_1 transition of the QDs, also observed in Fig. 8.

The possibility of fine-tuning the energy levels of quasi-0D nanostructures is a paramount tool for device design and implementation (Garcia et al., 1998).

When more excitation power is employed (Fig. 8), it is possible to observe higher excited states both for QD (E_1, E_2, E_3, E_4, E_5) and QR (E_1). At 500 mW, a clear state filling effect can be observed in both spectra. The relaxation of carriers between transitions of

Fig. 6 AFM profiles of an uncapped QD (black) and an uncapped Quantum Ring (blue) along $[1\bar{1}0]$ direction. The profile of the QR has been shifted vertically 2 nm to account for the thickness of the partial cap.

Fig. 7 (A) Photoluminescence spectra of a QD and a QR ensemble taken with a pumping power of 20 mW. The energy difference between the fundamental transition (E_0) is 220 meV, corresponding to the drastic change of shape and size from Quantum Dots (B) to Quantum Rings (C). This is a huge change in the confining potential that can be tuned on will.

Fig. 8 (A) Low T Photoluminescence spectra of QD and QR ensembles taken with a pumping power of 500 mW. At high pumping power a state filling effect can be observed in both spectra. The experimental spectra (symbols) have been fitted with six Gaussian function (green lines) with identical FWHM. This observation reveals a high quality, highly uniform ensembles of QRs (AFM in B) and QDs (AFM in C). The transition from the wetting layer can also be observed (red line). The spectra have been normalized to its maximum value and vertically shifted for clarity.

lower states (E_0) is not fast enough to drain the photo-created carriers, so higher transitions can be observed. This observation reveals a state filling effect of a high quality, highly uniform ensemble of nanostructures. The transition from the wetting layer can also be observed (red peak contribution) in both spectra.

Quantum Ring formation mechanism: Dynamical de-wetting & diffusive alloying

A key element for the explanation of ring formation is the competition between a dynamical de-wetting process with a diffusive Ga—In diffusive intermixing. De-wetting involves the presence of liquid indium, which has been demonstrated in the previous discussion in Sections “Quantum Dots” and “Formation and optical properties of Quantum Rings.” The liquification of InAs is driven by the minimization of the Gibbs free energy (Bottomley, 2002). There are theoretical results (Bottomley, 2002) showing that a biaxial epitaxial stress of InAs on GaAs(100) leads to a mixture of stress-free matter including a liquid phase of In and/or InAs. The driving force for this melting is the elastic energy (Bottomley, 2000; Garcia et al., 2000). It is expected that when QDs are partially covered, and consequently compressed, they undergo a phase transition into liquid phase and allows a de-wetting process (Lorke et al., 2002) that expels radially InAs from the QD.

Moreover, this effect has been observed (Silveira et al., 2001) to be independent of the temperature T in the 170–520 °C range. Therefore, the presence of stress-driven liquid InAs is a T independent process.

The uncapped dots are not liquid droplets (as distinct from the case of droplet epitaxy, Gurioli et al., 2019), they possess a 3D crystalline structure that is reflected in the RHEED pattern. They only become partially melted driven by the stress that the capping layer induces in the partially capped island. For taller dots this effect is more pronounced. This is the reason for using QD taller than 7 nm for self-assembling of Quantum Rings. There is a dynamical competition between de-wetting and alloying, that is why the GaAs growth rate of the capping layers plays an important role in the final size and properties of embedded QDs (Utrilla et al., 2018). The intermixing and alloying process is strongly temperature dependent. Therefore, by changing the temperature of the capping layer, we can achieve the formation of Quantum Rings or other types of nanostructures (Granados and Garcia, 2003).

Fig. 9A shows a scheme of a layer of QD that will be used for the ring formation. The materials involved are GaAs (substrate in blue, capping layer in yellow), InAs (dots in green), InGaAs QRs (in red) and arsenic vapor pressure (As, no color in Fig. 9), which is

Fig. 9 Schematic of QR formation. (A) An ensemble of self-assembled 3D InAs islands (green) on GaAs (blue). A cross section is depicted in B) showing Young's equation of the equilibrium forces for a liquid droplet of indium. When the QDs are partially capped (yellow layer in C) and a growth pause under arsenic (As) vapor is introduced, there is an unbalance of net forces in Young's equation creating a radial force (ΔF) that pulls out the material (D). At the same time at the base of the QD there is a strong temperature-dependent intermixing and alloying between In and Ga atoms which trends to freeze the eruption of the base of the QD (D). Under the right conditions (see text) an ensemble of Quantum Rings (red) is created (E and F).

always present. The figure shows a cross section through the middle of a QD which is also shown in Fig. 9B with a simple explanation of the equilibrium forces involved for the case of an indium liquid droplet on a solid interface. The surface tensions are described by Young's equation (see Fig. 9B). The in-plane surface tension of the interface GaAs—As ($\gamma_{\text{GaAs-As}}$, black) is compensated (Fig. 9B) to the sum of the surface tension $\gamma_{\text{InAs-GaAs}}$ of the InAs—GaAs interface (red) plus the horizontal component of the surface tension of the InAs—As interface (blue), i.e., $\gamma_{\text{InAs-As}} \cos \theta$. R. Blossey and A. Lorke have suggested (Blossey and Lorke, 2002; Lorke et al., 2002) that a change in the balance of surface free energy due to the thin capping layer (see Fig. 9C and D) creates an outward pointing de-wetting force. Comparing the equation shown in Fig. 9B and D, there is an unbalance radial net force $\Delta F = \gamma_{\text{InAs-GaAs}}(1 + \cos \theta)$ (assuming that $\theta = \theta'$) responsible for the material redistribution and results in a ring-shaped structure (Fig. 9E and F).

We have to consider that there is also a simultaneous Ga—In intermixing and alloying process (Joyce et al., 1998, 2000; Garcia et al., 1997) during partial capping of the QDs (Fig. 9D). The formation of an InGaAs alloy reduces the strain energy and prevents its strain-induced melt. It is strongly T dependent (Joyce et al., 1998) and quenches the mobility of In. There is a strong alloying at the edges of the base of the QD that prevents the complete depletion of the base of the QD (Fig. 9F).

Once the material redistribution has taken place during the growth pause, these nanostructures preserve their structure during further capping, as demonstrated by cross section transmission electron microscope (TEM) (Granados et al., 2005) and cross section scanning tunneling microscope (XSTM) measurements (Offermans et al., 2005). The growth pause during partial capping enhances the formation of InGaAs alloy, and reduces concentration of large amounts on indium in some parts of the InAs islands. These two facts contribute to preservation of the Quantum Ring shape during subsequent capping.

Aharonov-Bohm effect in Quantum Rings

These new types of self-assembled nano-volcanoes clearly show a large vertical reduction in the vertical confinement, as it is demonstrated by the conclusion derived from the measurements of optical properties (shown in Figs. 7 and 8). But what makes them particularly interesting is that they truly behave as Quantum Rings, i.e., they are defect-free, coherent nanostructures, that function in the Heisenberg quantum limit showing characteristic and unique properties of rings (Lorke, 2000). In 2007 Kleemanns et al. demonstrated by means of magnetization experiments, using a torque magnetometer, the presence of a persistent current carried by a single electron showing an Aharonov-Bohm (Aharonov and Bohm, 1959) effect. A sample was specifically designed and grown by MBE (Fig. 10A) and later characterized with state-of-the-art XSTM, (Fig. 10B). These data are used to create a very accurate description of the confinement potential that is used to make a theoretical model that perfectly reproduce the magnetometry measurements, taken at a temperature of 1.2 K and 4.2 K, of the first oscillation of the magnetic moment observed at a field of 14 T (Fig. 10C), also clearly observed in the inset to Fig. 10C, which displays the first derivative of the experimental magnetic moment

Fig. 10 (A) A test sample has been grown with 29 stacked layers of uncoupled Quantum Rings in a modulated doping structure adjusted to the density of QR to provide one electron per ring, (B) XSTM images of the cross-sections of two stacked Quantum Rings. The images have been taken along the two main principal directions. The images reveal the presence of indium (bright spots) in the center of the nanostructures, and a clear difference in the distribution of indium and the height of the rim between $[110]$ and $[1\bar{1}0]$ directions. (C) Oscillation in the magnetic moment per electron, measured by torsional magnetometry at 1.2 K and at 4.2 K, after subtracting the linear background from the signal. The inset shows the first derivative of the experimental magnetic moment with respect to B at $T = 1.2$ K. Modified with permission after Kleemans NAJM et al. (2007). Oscillatory persistent currents in self-assembled quantum rings. *Physical Review Letters* 99: 146808. Copyright 2007 by the American Physical Society.

with respect to B at $T = 1.2$ K. The observed oscillation magnitude of the magnetic moment per electron is remarkably large for the topology of these nanostructures, which are singly-connected, and exhibit a pronounced shape asymmetry along $[110]$ and $[1\bar{1}0]$. The XSTM images (Fig. 10B) show a nanoscale object which has a distribution of InAs material with no opening in the center. The InAs concentration of material resembles a “red blood cell” shape. What is outstanding is that the electron wave functions in such singly-connected material distribution are topologically identical to the electron wave functions in doubly-connected rings (Fomin, 2018b). Therefore, we can state that the electron states in self-assembled QRs are assigned to doubly-connected topology.

Conclusion

In summary, it is possible to fabricate self-assembled Quantum Rings grown by MBE by introducing a pause during the partial capping of a seed layer of QDs. We have shown that a large fraction of stress-induced melted liquid indium is present during the growth. Partial capping induces melting of InAs islands and promotes a de-wetting process that results in a nanoeruption. We describe and discuss the processes involved in their formation. The changes in shape and size lead to a drastic modification of the quantum confinement potential and enable the fabrication of Quantum Rings. We show a drastic reduction in vertical confinement revealed by a strong blue-shift in the photoluminescence spectra of highly uniform and high-quality ensembles of Quantum Rings. We demonstrate that they are defect-free coherent nanostructures that behave as Quantum Rings. Quantum Rings are very promising nanostructures with fascinating properties and possibilities to develop strategic areas of the next future quantum revolution.

Semiconductor QR-systems can be fabricated nowadays with a bottom-up approach (like self-assembly methods and vertical strain engineering) in combination with top-down techniques (like e-beam lithography and laser interferometric lithography) to

provide a great complexity of ordered ring systems. In particular, single and multiple QRs, ordered arrays of QRs, complexes of QRs in combination with other nanostructures have been created recently. For example, laser emission was early demonstrated using three vertically stacked layers of QRs (Suarez et al., 2004). Some other examples of QR arrays offer superior prospects in high density magnetic memory applications as magnetic random-access memory, recording medium, and other spintronic devices (Wen et al., 2007). An alternative to MBE for the growth of nanostructures is the use of droplet epitaxy (Heyn et al., 2011; Wu and Wang, 2014, 2018; Sanguinetti et al., 2014; Gurioli et al., 2019), which provides a great engineering flexibility for fabricating various topology interesting nanostructures which can be used for the implementation of ideal quantum light sources for quantum communication and photonics-based quantum computers.

Another emerging research field is the use of QRs as promising building block for metamaterials. A possible control over the electromagnetic response in QR composite metamaterials (Linden et al., 2004) made from metals and semiconductors is an attractive goal for further investigations. QR-metamaterials can be implemented ordering laterally the rings by strain engineering of a multi-layer InGaAs quantum-dot superlattice (Wu et al., 2012a). It is also shown that two-dimensional periodically aligned QR-arrays can be fabricated on high-index GaAs(311)B and GaAs(511)B surfaces (Wu et al., 2012b) (see Chapter 00361. Self-Organized Semiconductor Nanostructures (Quantum Dots, Quantum Rings and Their Arrays) by Marega, E., Jr. in the present Encyclopedia).

Also, another exciting future trend is the development of theory and fabrication technique for the implementation of Quantum Rings with quantum point contacts, which can be used for the development of quantum information devices using semiconductor nanostructures (Diago-Cisneros and Mireles, 2003; Nagasawa et al., 2013).

The possibility of using QRs as photon sources and detectors is based on their unique optical properties associated with the excitonic Aharonov–Bohm effect. Some works (Fischer et al., 2009) have theoretically conceived a technique to completely trap and store, and later release individual photons at will, by tuning magnetic and electric fields. Application of these QRs as light capacitors or buffers is expected in the fields of photonic computing and communications technologies (Fischer et al., 2009; Borunda et al., 2008).

A very interesting future emerging field could be the experimental demonstration of a higher spin stability in Quantum Rings than in a quantum dot. The relaxation and decoherence processes take place at a time scale that is sufficiently long for spin manipulation and readout (Zipper et al., 2011). This spin stability would allow to use QRs as spin qubits.

Engineering the wave-function in type II dot-ring structures electrically offers a great possibility to modify the g factor through an external bias, and is a very interesting approach for implementation of quantum-information solid state devices. (Nowack et al., 2007). Topology driven g factor tuning in type-II quantum dots (Llorens et al., 2019) is an example of novel, topology-driven resources for functionalization in quantum electronics.

Abstract

While a homogeneous aluminum crystal provides experimental validation of conventional *Bardeen-Cooper-Schrieffer* (BCS) superconductivity near zero temperature proposed in 1957 with a single small superconducting gap and a long range coherence length, today multiple realizations of nanoscale spatial heterogeneity have provided evidence for non-BCS multi-gap superconducting phase with high critical temperature where T_c maximum has been reached by tuning strain, dopants distribution, temperature treatments, local charge density heterogeneity, short range charge density waves, pseudo-Jahn-Teller polarons, and spin-orbit coupling. The lattice complexity controls the emergence of quantum macroscopic functionality at high-temperature. Therefore unveiling the nanoscale spatial conformations, the correlated disorder and the dynamical spatiotemporal fluctuations has been a fascinating adventure in these last years. Visualizing conformational nanoscale landscapes has been possible using advanced methodologies based on both high-precision X-ray measurements and advanced mathematical and statistical tools. Here we discuss the relations between the dynamical correlated disorder at nanoscale and the functionality in oxygen-doped perovskite superconducting materials. First, we deal with nanoscale textures of mobile interstitial oxygen; thus we show spatial correlations of oxygen ordering with short range charge density waves in perovskites high temperature superconducting compounds.

Key points

- To introduce the concept of nanoscale phase separation called superstripes
- To identify correlated disorder in doped perovskites
- To introduce complex self organization of oxygen interstitials
- To discuss scale free distribution of oxygen puddles and oxygen wires
- To introduce the superstripes landscape of short range charge density waves puddles
- To introduce synchrotron X-ray diffraction methods to unveil nanoscale complexity

Introduction

While phase separation (PS) was considered to be detrimental for conventional superconductivity in theory (Bardeen et al., 1957) it has been shown that a particular case of nanoscale phase separation called Superstripes (Bianconi et al., 1996; Bianconi et al., 1998; Bianconi, 2000; Bianconi, 2013) is the essential ingredient in the mechanism of high temperature superconductivity with different manifestations (Mazziotti et al., 2017; Mazziotti et al., 2021a,b, 2022). The heterogeneity of insulating and metallic nanoscale phases gives a two gap superconducting phase where the large and small superconducting gaps (Bianconi et al., 1998) shows a shape resonance belonging to the class of Fano resonances (Fano, 1961) driven by exchange interaction. Complexity in High Temperature Superconductors (HTS) and related materials has been unveiled by many experimental and theoretical works showing lattice fluctuations in perovskites (Thomas and Müller, 1968; Reihl et al., 1984; Glazer, 1972; Glazer, 1975; Howard and Stokes, 1998), superconductivity due to pseudo-Jahn-Teller polarons (Bianconi et al., 1996; Bednorz and Müller, 1986; Bednorz and Müller, 1988; Bednorz and Muller, 1990; Bishop et al., 1989; Keller et al., 2008; Mannhart et al., 1991; Innocenti et al., 2009; Agrestini et al., 2003; Della Longa et al., 1995), two electronic components (Müller et al., 1998; Khasanov et al., 2007) glassy phase (Deutscher and Müller, 1987) isotope effect (Weyeneth and Müller, 2020; Kochelaev et al., 2014; Bendele et al., 2017; Lanzara et al., 1999) phase separation (Muller and Benedek, 1993; Mihailovic et al., 1995; Liarokapis et al., 1996; Kaldis et al., 2012; Müller, 2000; Kremer et al., 1992; Kremer et al., 1993; Poulakis et al., 1996; Sigmund and Müller, 2012; Campi and Bianconi, 2019).

While disorder usually suppresses the superconducting critical temperature, T_c , in conventional superconductors, the manipulation of oxygen defects in cuprate perovskites like in $\text{La}_2\text{CuO}_{4+y}$ by thermal treatments (Fratini et al., 2010) or by X-ray photo induced effect, (Poccia et al., 2011) pumping and probing at same time the nanoscale textures has provided compelling evidence that the superconducting properties are enhanced by an optimum lattice inhomogeneity in High Temperature superconductors, HTS, with perovskites structure. The nanoscale phase separation related to the self-organization of defects has been found in $\text{YBa}_2\text{Cu}_3\text{O}_{6+y}$ (Campi et al., 2013; Ricci et al., 2013; Ricci et al., 2014; Zimmermann et al., 2003). Scanning nanoscale x ray diffraction has shown the coexistence of short range CDW puddles and oxygen rich puddles in $\text{HgBa}_2\text{CuO}_{4+y}$ tetragonal crystal with filamentary superconductivity at the interface (Campi et al., 2015; Campi and Bianconi, 2016). Interface superconductivity has been observed in several artificial perovskites superstructures (Campi and Bianconi, 2021). Recently, several theories have been proposed based on the presence in HTS of networks of nanoscale superconducting grains (Innocenti et al., 2009). The tendency toward electronic phase separation in strongly correlated multiband systems with polaronic and Fermi particles near a Mott transition is now well accepted. The Intrinsic phase separation can promote unconventional quantum phases also in chalcogenide superconductors $\text{A}_x\text{Fe}_{2-y}\text{Se}_2$ (Ricci et al., 2011; Ricci et al., 2015; Ricci et al., 2020) in Sc doped $\text{Mg}_{1-x}\text{Sc}_x\text{B}_2$ (Agrestini et al., 2004; Campi et al., 2006), in cobalt oxides (Drees et al., 2014) and in nikelate perovskites, $\text{La}_{2-x}\text{Sr}_x\text{NiO}_4$, with the formation of dynamic spin and charge density wave puddles (Ricci et al., 2021; Campi et al., 2022a,b).

Oxygen order in cuprates systems

Superlattices in YBCO

The $\text{YBa}_2\text{Cu}_3\text{O}_{6+y}$ system is made of an infinite layer cuprate, $\text{Y}[\text{Cu}(2)\text{O}_2]_2$, intercalated with the defective spacer oxide $[\text{BaO}]_2$ and $\text{Cu}(1)\text{O}_y$ chains. The oxygen defect ions $\text{O}-i_y$ in the chains partially fill the empty basal plane sites forming vacancies ordering in the $\text{O}(1)$ sites. The formation of the CuO chains can be detected as satellite superstructure streaks in the X Ray Diffraction patterns of $\text{YBa}_2\text{Cu}_3\text{O}_{6+y}$. We have first studied the *tetragonal to orthorhombic phase transition* in $\text{YBa}_2\text{Cu}_3\text{O}_{6+y}$ at $y = 0.33$ with $T_c = 7$ K, probing the metamorphic phase with local oxygen concentration $y = 0.5$ observed in the range $0.33 < y < 0.62$ and called Ortho-II (v. Zimmermann et al., 2003). The diffraction patterns in the (a^*, b^*) plane of $\text{YBa}_2\text{Cu}_3\text{O}_{6.33}$ show the diffuse streaks $q_{\text{ortho-II}}$ at $(h \pm 0.5, 0)$ due to nanoscale puddles made by $\text{O}-i$ ordering (see Fig. 1a). The equal intensity of horizontal and vertical streaks highlighted with the black rectangles indicate a phase made of the Ortho-II puddles where the a -axis is oriented both in the vertical and horizontal direction. A Pictorial view of the basal $\text{Cu}-\text{O}-i_y$ plane is show in Fig. 1b. Horizontal and vertical oxygen-rich metamorphic phase ($y = 0.5$), called Ortho-II, are intercalated by disordered oxygen-poor ($y < 0.33$) domains. Phase separation due to the spatial distribution of the (OII) superstructure has been visualized by scanning micro-X-ray diffraction using a 12-KeV energy and probing 1- μm thickness of the crystal surface. In Fig. 1c and d we show the color maps of the OII superstructure intensity and coherence length. The size of the Ortho-II oxygen chain puddles ranges from 3 (dark blue) to 12 nm (red) in the (a) a -axis direction. This system presents a further phase separation due to spin-up and spin-down sites, as calculated in the interfaces of the ASYNINI system (Ceder et al., 1991). The interfaces can be generated by an exploration process in which one moves clockwise on the edges with the simple rule that to its right is always a (+) site and to its left is always a (−) site in agreement with (Najafi and Tavana, 2016).

We have studied the temperature evolution of the symmetry in the ortho-II superstructure. In Fig. 1g we show the variation of the average structure of Ortho-II puddles in the (h, k) plane of $\text{YBa}_2\text{Cu}_3\text{O}_{6.33}$ measured in transmission mode. The variation of the size of the Ortho-II puddles oriented in the vertical (open squares red) and horizontal (open triangles) direction in the sample, during the warming cycle is shown in Fig. 1h. The difference between the size of vertical and horizontal Ortho-II puddles indicated by large filled (red online) dots (filled dots, blue online) in the heating (cooling) cycle shows a large value in the range $350 \text{ K} < T < 380 \text{ K}$ due to the spontaneous symmetry breaking in the fluctuation regime above 350 K. Increasing the $i-\text{O}_y$ content, we have investigated the spatial arrangement of Ortho-VIII puddles in $\text{YBa}_2\text{Cu}_3\text{O}_{6.67}$. Upon thermal treatments we were able to switch from a first network of oxygen defect striped puddles with OVIII modulation to a second network characterized by OXVI modulation and finally to a third network with puddles of OV periodicity. We have mapped the spatial evolution of the out of plane OVIII, OXVI and OV puddle nanosize distribution via scanning micro-diffraction measurements. In Fig. 2a we show thermal evolution of the OVIII oxygen stripe superlattice profile at $\eta(a^*) = 15/H = 24$ ($30/H = 48$) into the OV superstructure at $\eta(a^*) = 15/H = 25$ ($30/H = 50$), passing from the incommensurate OXVI superstructure. In order to monitor the microscopic evolution of OVIII domains into OXVI and OV during the thermal manipulation, we used μXRD with a beam about 1 μm in diameter by scanning the sample over an area of $160 \times 80 \mu\text{m}^2$. The maps of $\eta(a^*)$ and Probability Density Function (right panels) at three different temperatures during the thermal cycle where the system shows the OVIII, OV and OXVI phases are shown in Fig. 2b. We can observe the thermal cycle of the intensity, the average puddle size along a^* and along b^* . Starting from the FWHM_{XY} and the h_{XY} along a^* , measured at each $X-Y$ spatial position, we reconstructed the spatial maps of the *number of oxygen chains* (n) inside the puddles. Using the expression $n_{XY} = (1 - h_{XY})/\text{FWHM}_{XY}$, we calculate this quantity for OVIII, OXVI and the annealed OV puddles (see Fig. 2c). The number of oxygen chains decreases after the thermal heating cycle from OVIII to OXVI and increases again after the cooling in the OV puddles (but remains lower than in the OVIII phase).

Fig. 1 (a) The diffraction pattern in the (h,k) plane of $\text{YBa}_2\text{Cu}_3\text{O}_{6.33}$ ($T_c = 7$ K) measured in transmission mode on a 100- μm -thick sample with c axis oriented in the X-ray beam direction. Here, 20-KeV photon energy and 100- μm X-ray beam size have been used. The diffuse streaks $q_{\text{ortho-II}}$ at $(h \pm 0.5, 0)$ are superstructure satellites due to nanoscale puddles with Ortho-II structure made by O-i ordering after annealing at 300 K. The equal intensity of horizontal and vertical streaks highlighted with the black rectangles indicate a phase made of the Ortho-II puddles where the a -axis is oriented both in the vertical and horizontal direction. (b) Pictorial view of the basal $\text{Cu-O-}i_y$ plane of $\text{YBa}_2\text{Cu}_3\text{O}_{6.33}$. The small black dots are the $\text{Cu}(1)$ sites, and the large red dots are the oxygen defect ions $\text{O-}i_y$. Horizontal and vertical oxygen-rich metamorphic phase ($y = 0.5$) are called Ortho-II. The Ortho-II puddles are intercalated by disordered oxygen-poor ($y < 0.33$) domains. The black bar indicates 2-nm length scale. (c) OII intensity as seen by scanning micro-X-ray diffraction of a single crystal $\text{YBa}_2\text{Cu}_3\text{O}_{6.33}$ using a 12-KeV energy and probing 1- μm thickness of the crystal surface. The color map of: the OII superstructure intensity is plotted as a function of the illuminated spot position x - y in the sample surface, where x and y directions in the image correspond to the a and b crystallographic axis of the sample. The black bar indicates 20 μm length scale on the sample surface. (d) The puddle size (color) of the Ortho-II puddles is plotted as a function of the illuminated spot position xy in the sample surface. The size of the Ortho-II oxygen chain puddles ranges from 3 (dark blue) to 12 nm (red) in the (a) a -axis direction. The white bar indicates 20- μm length scale on the sample surface. (e) Temperature evolution of the $q_{\text{ortho-II}}$ satellite reflection profiles along h . The bright (red) and dark (blue) color corresponds, respectively, to the higher and lower intensities of the satellite diffraction spots. Variation of the average structure of Ortho-II puddles in the (h,k) plane of $\text{YBa}_2\text{Cu}_3\text{O}_{6.33}$ measured in transmission mode of a 100- μm -thick sample using an X-ray beam of 20-KeV photon energy and 100- μm size. (f) The variation of the size of the Ortho-II puddles transmitted in the vertical (open squares red) and horizontal (open triangles) direction in the sample, during the warming cycle. The difference between the size of vertical and horizontal Ortho-II puddles indicated by large filled (red online) dots (filled dots, blue online) in the heating (cooling) cycle shows a large value in the range $350 \text{ K} < T < 380 \text{ K}$ due to the spontaneous symmetry breaking in the fluctuation regime above 350 K. Reproduced from Campi G, Ricci A, Poccia N, Barba L, Arrighetti G, Burghammer M, ... Bianconi A (2013) Scanning micro-X-ray diffraction unveils the distribution of oxygen chain nanoscale puddles in $\text{YBa}_2\text{Cu}_3\text{O}_{6.33}$. *Physical Review B*, 87(1): 014517.

From the FWHM along c^* we calculated the out of plane domain size for every spot of the scanned map. Fig. 2d shows the real space map of the out of plane domain size (along c^*), before the heating (OVIII), at 390 K (OXVI) and after the cooling cycle (OV), respectively. These maps show the presence of clear intrinsic nanoscale heterogeneity in this cuprate superconductor. The OVIII probability density functions for the domain size distribution along c^* is relatively sharp, and varies from 7 to 9 nm. Upon heating, the OXVI phase shows instead a very broad distribution, that spans the 1–6 nm range. After the cooling cycle, the size distribution in the OV phase sharpens again, around the decreased average value of 3 nm, therefore indicating a certain recovered order. The overall behavior indicates a sensible response of the granular network to thermal treatment.

In order to understand how the microscopic reduction of the effective hole doping affects the superconducting properties, we studied the magnetic response of our sample across the superconducting transition before and after the thermal annealing, i.e., in the OVIII and in the OV phase. Fig. 3 shows the spot-to-spot charge density (p_{XY}) as a function of the number of oxygen chains (n_{XY}), inside the OVIII, OXVI and OV puddles. The charge density has been calculated considering the difference of the superlattice

Fig. 2 (a) Thermal evolution of the OVIII oxygen stripe superlattice profile at $\eta(a^*) = 15/H = 24$ ($30/H = 48$) into the OV superstructure at $\eta(a^*) = 15/H = 25$ ($30/H = 50$), passing from the incommensurate OXVI superstructure. The temperature ranges from 300 to 400 K. The reflections of the superstructures in the YBa₂Cu₃O_{6+y} crystal are measured using a large ($200 \times 200 \mu\text{m}^2$) beam at the ELETTRA storage ring. (b) (left panels) Probability Density Function and (right panels) maps of $\eta(a^*) = 30/H$ at three different temperatures during the thermal cycle where the system shows the OVIII, OV and OXVI phases. (c) (upper panels) Maps and (lower panel) Probability Density Function of the number of chains in the OVIII and OV phases. (d) (upper panels) Maps and (lower panel) Probability Density Function of the out of plane puddle size in the OVIII and OV phases. Panels c, d are reproduced from Ricci A, Poccia N, Campi G, Coneri F, Barba L, Arrighetti G, ... Bianconi A (2014) Networks of superconducting nano-puddles in 1/8 doped YBa₂Cu₃O_{6.5+y} controlled by thermal manipulation. *New Journal of Physics*, 16(5): 053030.

position along a^* (h_{XY}) with respect to the ortho-II (OII) phase following the relationship $p_{XY} h_{XY} = 0.5$, where the OII modulation corresponds to a periodicity of a filled CuO chain intercalated by one empty chain. The behavior has been fitted using an exponential model: $p_{XY} = 1 - \exp\{-(n_{XY} - n_0)/n_0\}/\xi_n$. Here n_0 and ξ_n are the minimum and the maximum number of chains present in the average puddle. We studied the magnetic response of our sample across the superconducting transition before and after the thermal annealing, i.e., in the OVIII and in the OV phase, by means of the VSM option in a PPMS 6000 from Quantum Design. A first measurement is made before any annealing procedure is carried out (OVIII phase), and shows the onset temperature of the diamagnetic screening (T_c) to be about 66 K. The subsequent measurements are made upon thermal annealing at 380 K (OV phase), with increasing dwell time of 30, 60, 90 and 150 min. In all these cases T_c decreases by about 2 K.

At this iO_y content, we have investigated the spatial arrangement of Ortho-VIII puddles at different length scale using scanning micro and nano X-ray diffraction pushing the measurement of superstructure reflections down to unprecedented real space resolution of 300 nm. In particular, comparing maps obtained from measurements at different spatial scale ($1 \times 1 \mu\text{m}^2$ vs. $300 \times 300 \text{ nm}^2$), we are able to show how the inhomogeneity appears more clearly at smaller scale, indicating such local structural inhomogeneity as an intrinsic property in these materials. The diffuse streaks shown in Fig. 4a provide direct evidence for nanoscale puddles in the basal a - b plane with Ortho-VIII modulation with a substantial disorder in the stacking of full and empty chains

Fig. 3 (a) Charge density (hole concentration p) as a function of the number of oxygen chains, inside the OVIII, OXVI and OV puddles. The dotted curve is a fit using a model: $p = 1 - \exp\{-[(n - n_0)/n_0]/\xi_n\}$, where n_0 and ξ_n are the minimum and the maximum number of chains present in the average puddle. (b) Left scale: zero field cooling (ZFC) diamagnetic response of YBCO upon thermal cycles in an external applied field $H = 20$ Oe. Blue filled circles: signal before any thermal annealing. Yellow-red squares: the magnetic moment upon sample annealing at 380 K with increasing dwell time of 30, 60, 90 and 150 min. Right scale: numerical derivative of the magnetic moment. Upon thermal cycling the onset of superconducting shielding decreases by about 2 K. Adapted from Ricci A, Poccia N, Campi G, Coneri F, Barba L, Arrighetti G, ... Bianconi A (2014) Networks of superconducting nano-puddles in 1/8 doped YBa₂Cu₃O_{6.5+y} controlled by thermal manipulation. *New Journal of Physics*, 16(5): 053030.

Fig. 4 (a) The X-ray diffraction pattern shows diffuse superstructure satellites at 3/8 and 5/8 positions, their profile along h is plotted. (b) Room temperature diffraction pattern collected using a transmission geometry. The CuO chains superlattice reflections $q_{\text{Ortho-VIII}}(a^*)$ 5(3/8,k,0) and $q_{\text{Ortho-VIII}}(a^*)$ 5(5/8,k,0) are highlighted in the empty yellow box. (c) Pictorial view of the basal Cu-Oi_y plane of YBCO. The small gray dots are the Cu(1) sites and the large yellow dots are the oxygen ions O_i in defective basal plane. The pictorial view of oxygen ordered metamorphic phases called Ortho-VIII, with formal oxygen content $y = 0.625$ shown in the pink filled rectangles, are embedded in the disordered background with an oxygen content slightly larger than the average oxygen content 0.67. (d) The Ortho-VIII mapping of the domain size along a^* . Here the variation is more pronounced, indeed, the intense red-yellow peaks in the two-dimensional color map represent locations in the sample with high strength of Ortho-VIII ordering, and dark blue indicates spots of disordered Ortho-VIII domains. (e) Probability density function of the domain size along a -axis obtained by the microbeam of $1 \mu\text{m} \times 1 \mu\text{m}$ (filled circles) and the nanobeam $300 \text{ nm} \times 300 \text{ nm}$ (filled squares) measurements. (f) The Ortho-VIII mapping of the domain size along c^* . (g) Probability density function of the domain size along c -axis obtained by the microbeam of $1 \mu\text{m} \times 1 \mu\text{m}$ (filled circles) and the nanobeam $300 \text{ nm} \times 300 \text{ nm}$ (filled squares) measurements. Adapted from Ricci A, Poccia N, Campi G, Coneri F, Caporale AS, Innocenti D, ... Bianconi A (2013) Multiscale distribution of oxygen puddles in 1/8 doped YBa₂Cu₃O_{6.67}. *Scientific Reports* 3(1): 1–6.

along the c direction. The nanoscale size of Ortho-VIII puddles embedded in a disordered medium is shown as pictorial view in Fig. 4b representing the basal Cu-O plane of YBCO. The Ortho-VIII puddles are made of alternated 5 filled and 3 empty oxygen wires every 8 rows. The number of oxygen ions per unit in the puddles is $6.625 = 6.5 + 0.125$ that gives exactly $1/8$ holes per Cu site in the $\text{Y}(\text{CuO}_2)_2$ bi-layers with Cu^{2+} ions in the chains of the basal plane. Since the average oxygen concentration is $6.67 = 6.5 + 1/6$ the hole doping in the disordered background is larger than $1/8$. We reconstructed the 2D maps from the collected nXRD diffraction patterns, each one for a different spatial x - y position (a - c plane) of the sample.

Fig. 4c shows the 2D plots of the domains size variation along a crystallographic direction. The color extends from dark blue to dark red, respectively associated to 5 and 12 nm. In addition, the heterogeneous granular structure of the dopants, unveiled by the employ of a nanobeam, shows the relevance of the spatial resolution of the probe on the sample. Statistical analysis has been used to quantify the size distributions of the Ortho-VIII puddles as seen by (blue dots) scanning micro and (red squares) nano X-ray diffraction experiments. Fig. 4d shows the probability density function (PDF) of the Ortho-VIII puddles sizes along the crystallographic a -axis, observed using a beam of (blue dots) $1\text{ }\mu\text{m}$ and 300 nm of diameter. The distribution of the puddles is nearly symmetric as seen with a resolution of $1\text{ }\mu\text{m}$ while with 300 nm X-ray beam it shows a remarkable asymmetric fat tail, although the average value is comparable. Similar behavior is observed along the c direction- Fig. 4e and f show the map and the probability density function of the Ortho-VIII puddles sizes along the c crystallographic direction. The size of the puddles in the transversal direction from the CuO_2 planes is nearly symmetric while the distribution of sizes measured by the 300 nm nXRD probe, shows a remarkable fat tail. Also in this case the maps obtained by μXRD and the nXRD are in agreement for the average size of domains which is around 8 nm . The standard deviation is 0.4 nm for the $1\text{ }\mu\text{m}$ X-ray probe and 0.6 nm for the 300 nm X-ray probe.

Scale free distribution of oxygen wires in YBCO

The O-i textures from microscale to mesoscale have been studied by Scanning micro XRD measurements ($\text{S}\mu\text{XRD}$) and Scanning nano XRD measurements (SnXRD) to enhance the spatial resolution. The O-i maps measured in $\text{S}\mu\text{XRD}$ and SnXRD show rich stripe-ordered O-i (yellow regions) embedded in a matrix of disordered O-i (black regions), as shown in Fig. 9a and b, respectively. In order to characterize this inhomogeneity, we have computed the Probability Density Function, PDF, of the streak intensity for both $\text{S}\mu\text{XRD}$ and SnXRD . The PDF has been modeled by a power law behavior given by $\text{PDF}(I_{\text{streak}}) = C \cdot I_{\text{streak}}^{-\alpha}$. We find the critical exponent $\alpha = 2.0 \pm 0.1$ at both micron and mesoscale. I_{streak} values range from values smaller than 1 in the poor oxygen wires regions to values larger than 103 in the richer oxygen wires zones. This means that a scale-free organization of O-i is present in the sample, as already found at nanoscale in cuprates HTS. However, we observe that in the $\text{S}\mu\text{XRD}$ maps the size of oxygen wires domains does not exceed the single pixel size corresponding to an area of $1 \times 1\text{ }\mu\text{m}^2$ given by the scanning beam size. This limitation has been overcome by enhancing the real space resolution in XRD setup using SnXRD where the beam size has been reduced to $0.1 \times 0.3\text{ }\mu\text{m}^2$. Indeed, in this case the submicron structural features of oxygen wire rich domains can be appreciated (see Fig. 5b).

Fig. 5 (a) Logarithmic spatial map of streak intensity extracted by $\text{S}\mu\text{XRD}$ with $1 \times 1\text{ }\mu\text{m}^2$ spatial resolution. The rich stripes-ordered O-i (yellow regions) are anticorrelated with CDW rich domains (black regions). The bar corresponds to $10\text{ }\mu\text{m}$. (b) SnXRD spatial map measured with $0.1 \times 0.3\text{ }\mu\text{m}^2$ of streak intensity in logarithmic scale. Here we can appreciate the interface (red regions) between the rich stripes-ordered O-i (yellow regions) and CDW puddles (black regions). The bar corresponds to $1\text{ }\mu\text{m}$ and the size of the map corresponds to the size of the white rectangle in (a). (c) Plot of the Probability Density Function of rich stripes-ordered zones relative to the $\text{S}\mu\text{XRD}$ (open squares) and SnXRD (full circles) maps in (a) and (b). Both distributions have the power law exponent $\alpha = 2$. Adapted from Campi G, Mazziotti MV, Jarlborg T, Bianconi A (2022b) Scale-free distribution of oxygen interstitial wires in optimum-doped $\text{HgBa}_2\text{CuO}_{4+y}$. *Condensed Matter*, 7(4): 56.

Charge density waves and lattice defects

LCO—Correlated disorder and phase separation in $\text{La}_2\text{CuO}_{4+y}$

$\text{La}_2\text{CuO}_{4+y}$ is one of the simplest perovskites, where y oxygen interstitial ions (O-i) in the rocksalt $[\text{La}_2\text{O}_{2+y}]$ are intercalated by $[\text{CuO}_2]$ layers. The high brilliance of modern synchrotron photon sources allows to detect weak satellite peaks in X Ray Diffraction measurements, which are associated with superstructures, due to oxygen interstitial O-i dopants and electronic modulations, named charge-density waves (CDW). CDWs incommensurate diffuse satellites with wave vector $q_{\text{CDW}} = 0.21b^* + 0.29c^*$, coexisting with commensurate O-i satellites displaced by $q_{\text{O-i}} = 0.25b^* + 0.5c^*$ characterized by a different staging, that is, their c^* component. Indeed, O-i and CDW have staging $c^* = 0.5$ and $c^* = 0.29$, respectively, as indicated by the white and red arrows, respectively in Fig. 6a. The commensurate O-i, with $q(b^*) = 0.25$ and $q(c^*) = 0.5$ ordering, consists of the domains ordered with periodicity of $1/q\ b^* = 4$ and $1/q\ c^* = 2$ unit cells along b and c direction, respectively. On the other hand, the incommensurate CDW, with $q\ b^* = 0.21$, with a long period about $9/42$ ordering, consisting in the mixture of the 4 and 5 charge order, i.e., alternating periodicity of 4 and 5 lattice units along the b direction. The O-i and CDW ordering is schematized in Fig. 6b. We have found that these ordered domains are characterized by a strong spatial anticorrelation: oxygen-rich regions, where the system is in the over-doped metallic phase with low density of CDW, are intercalated with oxygen-poor region in the underdoped phase with high density of CDW. Fig. 6c shows the map of difference between the intensity of O-i and CDW diffraction satellites. The O-i are located in the $1/4, 1/4, 1/4$ site, and form commensurate stripes in the La_2O_2 structure, intertwined with incommensurate lattice CDW domains (Poccia et al., 2012). Indeed, we observed micron size puddles of blue metallic oxygen-rich regions, separated by red CDW-rich zones, by a filamentary percolating interface, indicated by white space.

The different intensity of O-i and CDW superstructure measured by $\text{S}\mu\text{XRD}$ is shown in Fig. 7a. A common and intriguing feature of quantum materials is that their emerging properties can be easily manipulated by weak external stimuli, such as temperature gradient, strain, and photon illumination. Due to the mobility of oxygen interstitials (O-i), our systems present structural conformational landscapes. The maps in Fig. 7b show two different O-i distributions, obtained with two different thermal treatments; the first one shows the maximum critical temperature ($T_c = 40\text{ K}$) and the second presents a macroscopic phase separation with two critical temperatures, $T_c = 16\text{ K}$ and 32 K (Fratini et al., 2010). In both samples, the probability density function of O-i satellite intensity follows an exponentially truncated power-law distribution, given by.

$$P(x) = x - \alpha \exp(-x/x_0),$$

where α is the critical exponent and x_0 is the cut-off. The critical exponent, α , results to be 2.6, both in the high- T_c (a) and low- T_c (b) conformations, indicating the fractal nature of O-i arrangement. On the other hand, the cut-off, x_0 , is larger for the high- $T_c = 40\text{ K}$ sample, as can be seen in Fig. 7c. This means that a larger extent of O-i satellite intensity with fractal geometry favors a higher T_c (Fratini et al., 2010).

Fig. 6 (a) XRD image of b^*c^* plane in the reciprocal lattice of the $\text{La}_2\text{CuO}_{4.1}$ sample. We observed several superstructures surrounding the indicated Bragg peaks 006, and 008, due to O-i ordering and charge-density waves (CDW). The arrows indicate the O-i and CDW superlattices. (b) Lattice modulations corresponding to CDWs and O-i superstructures. (c) Map difference between the normalized intensities of both CDW and O-i satellites in $\text{La}_2\text{CuO}_{4.1}$. CDW puddles are dominant in red regions, while the O-i stripes are dominant in the blue zones. The lattice modulations corresponding to CDWs and O-i superstructures are depicted. The interface (white region) between CDW-rich and O-i-rich regions gives the percolating pathways where supercurrent is expected to flow. The white bars correspond to $5\ \mu\text{m}$. Fig. 7 (a) Map difference between the normalized intensities of both CDW and O-i satellites in $\text{La}_2\text{CuO}_{4.1}$. CDW puddles are dominant in red regions, while the O-i stripes are dominant in the blue zones. The interface (white region) between CDW-rich and O-i-rich regions gives the percolating pathways where supercurrent is expected to flow. The white bars correspond to $5 \mu\text{m}$. (b) Spatial distribution of the O-i superstructure intensity for two different conformations in $\text{La}_2\text{CuO}_{4.1}$ samples, with $T_c = 40$ K (upper panel) and $T_c = 16$ and 32 K phases (lower panel) in a $500 \times 400 \mu\text{m}^2$ area. The bar corresponds to $50 \mu\text{m}$. (c) The rescaled probability distribution, $x^2 P(x)$, of the O-i superstructure intensity for the two samples. The cut-off, x_0 , increases from 8 ± 1 in the low- T_c conformation to 31 ± 2 in the high- T_c conformation. The rescaled distributions collapse on the same universal curve (black solid line). Adapted from Campi G, Bianconi A, Joseph B, Mishra SK, Muller L, Zozulya A, ... Ricci A (2022) Nanoscale inhomogeneity of charge density waves dynamics in $\text{La}_2\text{-xSr}_x\text{NiO}_4$. *Scientific Reports* 12: 15964.

Hg1201—Correlated disorder and phase separation in $\text{HgBa}_2\text{CuO}_{4+y}$

$\text{HgBa}_2\text{CuO}_{4+y}$ has a single CuO_2 plane with tetragonal crystal symmetry. The oxygen interstitial ions (O-i) form atomic stripes in the spacer layer $[\text{HgO}_y\text{Ba}_2\text{O}_2]$ between $[\text{CuO}_2]$ planes. We have measured the diffuse scattering associated with both CDW and oxygen interstitial arrangement in the lattice, as shown in Fig. 8a. Resolution-limited streaks connecting the Bragg peaks, due to atomic O-i stripes in the HgO_y spacer layers, have been measured in agreement with previous experiments (Izquierdo et al., 2011; Izquierdo et al., 2021).

Different charge ordering satellites have been detected, in Fig. 8 we report the analysis of the temperature and spatial distribution of the satellite with wave-vector $q_{\text{cdw}} \approx 0.23a^*$ appearing near Bragg peaks at high momentum transfer, which has been assigned to condensation of paired pseudo-Jahn Teller polarons (Bianconi et al., 1990) at the pseudo-gap temperature (Lanzara et al., 1999) forming nanoscale CDW puddles (Campi et al., 2023) called Q-balls (Mukhin, 2023). The oxygen interstitials ordering with the atomic wires formation appears below $T_{\text{O-i}} = 350$ K in Hg1201 as shown in Fig. 8. The striped charge density wave puddles made by Q-balls appear below $T_{\text{cdw}} = 240$ K (see Fig. 8b) which is close to the pseudo-gap temperature. Near different Bragg peaks we have

Fig. 8 (a) XRD image of a a^*c^* plane in the reciprocal lattice of the Hg1201 sample. We observed both streaks due to O-i ordering (left panel) and diffuse satellites due to polaronic charge-density waves (right panel). (b) Temperature dependence of O-i and polaronic CDW. The onset of oxygen ordering, $T_{\text{O-i}}$, and polaronic charge ordering T_{CDW} are indicated. (c) Map difference between the normalized intensities of both polaronic short range CDW and CDW satellites puddles dominant in red regions, while the O-i stripes are dominant in the blue zones. The lattice modulations corresponding to CDWs and O-i superstructures are depicted. The interface (white region) between CDW-rich and O-i-rich regions gives the percolating pathways where supercurrent is expected to flow. The white bars correspond to $5 \mu\text{m}$. Panel c adapted from Campi G, Bianconi A, Joseph B, Mishra SK, Muller L, Zozulya A, ... Ricci A (2022) Nanoscale inhomogeneity of charge density waves dynamics in $\text{La}_2\text{-xSr}_x\text{NiO}_4$. *Scientific Reports* 12: 15964.

Fig. 9 (a) Map difference between the normalized intensities of both CDW and O-i satellites. CDW puddles are dominant in red regions, while the O-i stripes are dominant in the blue zones. The bar corresponds to 5 μm . (b) Color plot of the map of the (left panel) O-i streak intensity and (right panel) charge-density waves (CDW) peak in $\text{HgBa}_2\text{CuO}_{4.12}$. (c) Probability density function, calculated from the O-i streaks and CDW intensity map in (a,b), showing a power-law behavior. (d) Pictorial view of the free electrons liquid flowing in the interstitial space left by CDW crystalline puddles. The CDW crystalline puddles form inhomogeneous spatial patterns giving rise to a new non-Euclidean geometry in the interstitial space left by the crystals of electrons. The free electrons, which do not crystallize, form Cooper pairs flowing along paths in the interstitial space at low temperatures. Panels a, b, c are reproduced from Campi G, Bianconi A (2021) Functional nanoscale phase separation and intertwined order in quantum complex materials. *Condensed Matter* 6(4): 40. Panel d is reproduced from Campi G, Bianconi A (2016) High-temperature superconductivity in a hyperbolic geometry of complex matter from nanoscale to mesoscopic scale. *Journal of Superconductivity and Novel Magnetism* 29(3): 627–631.

found different CDW satellites with lower ordering temperature $T_{\text{onset}} = 170 \text{ K}$ and $q \approx 0.28a^*$ which are known to appear near the $(h,k,0)$ Bragg peaks and have been assigned to static long range CDW. The spatial mapping shows inhomogeneity with a negative correlation between O-i order and the charge density wave puddles. The O-i atomic striped domains are phase separated from polaronic CDW (Q-balls) and long range CDW generating a percolating filamentary interface indicated by white space in Fig. 8c.

The spatial anticorrelation is well depicted in the “difference map” between CDW peaks and O-i-diffuse streaks in Fig. 9a. The poor CDW regions on the CuO_2 basal plane correspond to O-i-rich regions on the HgO_y layers. In Fig. 9b we show the maps of the integrated intensity of CDW peak and oxygen O-i diffuse streaks, respectively, as seen by μXRD measurements. Both O-i and CDW maps are spatially inhomogeneous, and their PDF is well modeled by a power-law behavior also in this case, as shown in Fig. 9c. The critical exponents in the two intensity distributions are 1.8 ± 0.1 and 2.2 ± 0.1 for the O-i and CDW, respectively.

Conclusion

The use of scanning micro-X-ray diffraction has provided compelling evidence for the emergence the interface space at mesoscopic scale with hyperbolic geometry favoring superconductivity in cuprate superconductors (see Fig. 9d). The hyperbolic space has recently been found to play a key role in different fields looking for the emergence of order in complex systems ranging from network theory to quantum gravity (Krioukov et al., 2012; Wu et al., 2015). The role of a spatial hyperbolic geometry in disordered media is known to be of high relevance in the design of new metamaterials showing a negative dielectric constant, as well as in the manipulation of complex light in optical metamaterials (Barthelemy et al., 2008; Bertolotti et al., 2012; Zeng et al., 2013; Esslinger et al., 2014). The hyperbolic space has recently been shown to influence critical phenomena (Mnasri et al., 2015). The search for complex materials with zero or negative dielectric constant has been one of the road maps proposed for the amplification of the superconducting critical temperature to reach room temperature superconductivity (Chu et al., 2005; Smolyaninov, 2014; Smolyaninova et al., 2014; Poddubny et al., 2012). The experiments show a hyperbolic space in the mesoscale of cuprates but it could be present also in pressurized sulfur hydride superconductors (Bianconi and Jarlborg, 2015), iron-based superconductors (Ricci et al., 2011; Ricci et al., 2015), and diborides (Campi et al., 2006) which all show local lattice fluctuations.

Abstract

Focused Ion Beam Induced Deposition or Focused Electron Beam Induced Deposition are direct-write nanolithography techniques that make use of a focused beam of charged ions or electrons to pattern nanometer resolution materials at a specific location. The physical interactions between the ions or electrons and the atoms of the substrate surface and the precursor molecules delivered to the process chamber are exploited for the additive nanofabrication of different materials in all three dimensions. In this chapter, the fundamentals of the techniques are outlined, a selection of materials grown with these additive nano-manufacturing techniques are reviewed. Additionally, a special emphasis is placed on examples of direct-writing of nano-superconductors in all three dimensions and a selection of their potential applications is described.

Key points

- Direct-write nanofabrication method, fabrication and properties of 1D, 2D and 3D nano-superconductors.
- Direct-write nanolithography method.
- Properties of 1D, 2D and 3D nano-superconductors.
- Preparation of superconducting devices and circuits.

Introduction

The incessant need to manufacture more sophisticated and powerful electronic devices every day has been achieved thanks to the miniaturization of integrated circuits, being key elements in these devices. However, higher processing power on these devices implies a higher power consumption. Therefore, the fabrication and study of nanoscale materials could shed some light on

[☆]*Change History:* August 2022. R Córdoba prepared the update. Figs. 1-6 are updated.

fundamental physical problems and solutions to today's limited electronics. This requires the development of a wide range of nanofabrication techniques.

In this context, Focused Ion Beam Induced Deposition (FIBID) or Focused Electron Beam Induced Deposition (FEBID) are direct-write nanolithography techniques that make use of a focused beam of charged ions (FIB) or electrons (SEM) to grow functional nanomaterials with complex shapes in all three dimensions at a specific location (Orús et al., 2020; Utke et al., 2008; van Dorp and Hagen, 2008). The best achieved resolution is 3 nm (van Kouwen et al., 2009) and the use of masks or resists is not required in contrast to more common nanofabrication techniques such as electron beam lithography (Fig. 1).

Some common applications of this FIB/SEM technology have been developed and integrated in the semiconductor industry, such as integrated circuit fabrication, photolithographic mask repair (Jonckheere et al., 2011), circuit editing (Martínez-Pérez et al., 2009), and the fabrication of very thin samples used in transmission electron microscopy (Giannuzzi and Stevie, 2005; Reyntjens and Puers, 2001).

Additive nano-manufacturing using FIBID and FEBID

Fundamentals of FIBID and FEBID

In the 1970s, FIB technology established itself as a solid approach within the nanolithography scene (Orloff and Swanson, 1978, 1975; Seliger et al., 1979; Seliger and Fleming, 1974), representing the ability to obtain, conduct, and focus a beam of charged ions at the nanometer scale for various purposes. Furthermore, the ability of SEM-induced processing for patterning was also inferred in the 1970s by the decomposition of adsorbed contaminants on a substrate leading to deposition of materials while the electron beam was scanning the substrate (Broers et al., 1976).

In the case of the FIB, as the beam is scanned over a material, several ion-matter interactions take place, such as the secondary electrons, secondary ions, sputtered atoms, backscattered ions, implanted ions, amorphized atoms, etc. These interactions result from the conservative transfer of energy and momentum from ions to atoms in the solid material (Fig. 2a). Secondary first-order electrons result from irradiation with a primary beam, while secondary second-order electrons emerge as a consequence of irradiation by backscattered ions away from the impact point of the primary beam.

In the case of the SEM, in the electron beam irradiation, high energetic electrons interact with the atoms of the material producing secondary electrons, backscattered electrons and X-ray signals (Fig. 2b). Similarly, to ion-matter interactions, secondary first-order electrons result from irradiation with a primary beam, while secondary second-order electrons emerge as a consequence of irradiation by backscattered electrons.

The generation of secondary electrons in materials is of vital importance in FIB/SEM microscopy for several reasons: (1) for the topographic contrast of the images; (2) for the material growth in FIBID and FEBID techniques.

An FIB/SEM in combination with a gaseous precursor adsorbed to the substrate surface, known as FIBID and FEBID techniques, are used to induce a partial decomposition of the precursor molecules, with subsequent material deposition at a specific location and nanoscale resolution. FIBID and FEBID processes are typically carried out on equipment that combines an FIB column with an SEM, known as FIB/SEM microscopes, and a gas injection system that is used to deliver the precursor molecules into the process chamber. Although, FIBID can also be performed on dedicated equipment known as FIB instrument and FEBID can be performed on a conventional SEM.

Specifically, for additive nano-manufacturing, FIB/SEM, FIB and SEM instruments have three main components: an ion and/or an electron column, a gas injection system and a process chamber. The column has in its upper part an ion source or electron tip, from which the ions/electrons are extracted, while in the lower part it has other elements that serve to accelerate them, focus them,

Fig. 2 (a) Sketch of the most important ion-solid matter interactions in FIB processing. (b) Sketch of the most important electron-solid matter interactions in SEM processing.

form the beam (beam diameters of <0.5 nm for SEM, of 5 nm for Ga^+ FIB and of ≈ 0.3 nm for He^+ FIB), and scan over a substrate surface in a controlled way. The gas injection system has a precursor reservoir and a series of elements that end in a nozzle, from where the precursor is delivered in gaseous phase to the process chamber to perform FIBID/FEBID near the focused beam incident point and the substrate surface. The process chamber is equipped with a platform that holds the substrate, several image detectors and other components to keep it under vacuum.

In general, the beam-scanned patterns in FIBID/FEBID and in FIB/FEB-induced processing are created by a series of closely spaced beam spots. The FIB/FEB remains for each spot size for a certain time (dwell time) and then moves on to the next. The pattern scan is repeated after the refresh time for a series of passes to deliver the required dose of ion/electron to the substrate surface. The beam spot has a Gaussian profile with a minimum size determined primarily by the beam current. The flexibility of the beam scanning allows one to define arbitrary shapes such as straight lines and areas, curvilinear lines and areas, polygons, etc. (Fig. 3) (Harriott, 1993).

In additive nano-manufacturing using FIB or SEM (Utke et al., 2012, 2008; Shorubalko et al., 2016; van Dorp and Hagen, 2008), FIB or FEB is scanned drawing a pre-defined pattern on a material surface, generating secondary electrons which induce the partial decomposition of precursor molecules into volatile compounds and non-volatiles. Volatile compounds are pumped out of the vacuum chamber, while non-volatile ones are deposited on the surface, creating nanomaterials in a single step (Fig. 4). FIBID or FEBID provides a working resolution range from up to hundreds of μm down to a single nm. It offers great adjustability and ease of use in terms of patterning of complex geometries at specific locations in a substrate. Its flexibility in terms of shape and its ultra-high

Fig. 3 Diagram of FIB/FEB scanning of a rectangular pattern. This pattern is scanned by serially exposing 54 beam spots, having a Gaussian profile, for a certain dwell time with a pitch-x and pitch-y equal to the spot size. The scanning is performed in serpentine mode. The pattern repeats for a series of passes after the refresh time.

Fig. 4 (a) Principle of FIB induced deposition using a gas injection system for local deposition of 3D nanostructures by dissociating the physisorbed molecules. Gas related processes include adsorption/desorption and surface diffusion to replenish the FIB dissociated adsorbates. Note that deposition only occurs when the sputter yield is smaller than the deposition yield. (b) Physical processes involved in the principle of FEBID. Panel (A): Shorubalko, et al. resolution (20–30 nm for Ga^+ FIBID, 10 nm for He^+ FIBID and 30 nm for FEBID) make it fascinating for applications that require unique and precise planar or 3D designs (Fig. 1).

The most relevant experimental parameters that govern FIBID and FEBID are listed below:

- the acceleration voltage is the potential difference used to accelerate ions/electrons along the column. In general, higher acceleration voltages produce higher resolution nanostructure growth and lower growth rate.
- the beam current is the value of the charge delivered to the substrate. Typical values of beam current are generally in the pA-nA range.
- the dwell time is the time the beam remains at each point during the scan.
- the dose is a quantification of the charge received by a material per unit area in a given period of time.
- the pitch is the distance between two consecutive points in a pattern. For areas, a different pitch can be defined for the x - and y - axis.
- the scanning strategy refers to the path of the beam within a pattern.
- the number of passes is the number of complete scans of the pattern.
- the refresh time is defined as the time required for the precursor gas molecules to replenish between passes.
- the volume per dose is the grown material volume per total charge.

Other experimental parameters, such as the ion species, the substrate material, the pattern dimensions and geometry, the gas injection nozzle position, the precursor molecule (vapor pressure, sticking coefficient to the surface, residence time, sublimation temperature), the base pressure in the vacuum chamber and during growth process, must be carefully selected for the successful additive nano-manufacturing of nano-objects.

The decomposition process of a precursor and, therefore the FIB/SEM-induced deposition rate strongly depends on several terms indicated in the following equation (Utke et al., 2008):

$$\frac{\partial n}{\partial t} = sJ \left(1 - \frac{n}{n_{ML}} \right) + D \left(\frac{\partial^2 n}{\partial r^2} + \frac{1}{r} \frac{\partial n}{\partial r} \right) - \frac{n}{\tau} - \sigma f n \quad (1)$$

where molecule-surface adsorption, molecule-surface diffusion, molecule-surface and/or ion-stimulated desorption and molecule dissociation terms are sequentially listed. The adsorption term is governed by the flux of molecules in the vapor phase, while the desorption term is governed by the residence time of the molecules, and in the case of FIBID includes the ion–molecule energy transfer. The latter interactions depend on the velocity and mass of ions, such as interactions of the molecule with lighter ions (i.e., He^+) result in its electronic excitation, while those with heavier ions (e.g., Ne^+ and Ga^+) are mainly governed by nuclear stopping power with weak contributions from electronic excitation and heating of the molecule (Indrajith et al., 2019). The diffusion depends on the type of precursor molecules and the substrate (Utke et al., 2008). Finally, the dissociation term depends on the energy-integrated dissociation cross section (σ) and the ion/electron flux.

However, in FIBID process, the contribution of ion implantation, local heat generation, material redeposition, deposition induced by secondary second-order electrons, FIB-induced milling or sputtering must be taken into account. As an example, the use of low beam current and a short dwell time are beneficial in minimizing milling effects with respect to deposition. Thus, the growth rate of FIBID/FEBID can be defined with the following equation:

$$R = \frac{V\sigma f}{t_d} \int_0^{t_d} n \, dt - R_s \quad (2)$$

where R_s is the milling/sputtering rate caused by ion irradiation.

FIBID/FEBID occur in either an electron-limited regime, or a precursor-limited regime depending on the balance between the number of secondary electrons reaching the substrate surface and the amount of precursor molecules available at the surface for decomposition.

Since these additive nano-manufacturing techniques (Utke et al., 2012, 2008) induce partial decomposition of precursor molecules, FIBID/FEBID nanostructures commonly consist of the target element (usually a metal), carbon and oxygen (from the precursor), implanted ions (when heavy ionic species are used) and other contaminant species, which generally impair its functionality.

Materials grown with FIBID

This sub-section reviews the most significant materials grown with FIBID (Table 1). At least three different electrical conductivity regimes are reported for these materials: semiconducting, metallic, and low-temperature superconducting.

Platinum

In this regard, semiconducting and metallic Platinum-Carbon deposits were grown using MeCpPtMe_3 and CpPtMe_3 as precursors, respectively. This Pt-C material is regularly used as a protective layer against ion-induced effects in nanofabrication for cross-sectional FIB/SEM imaging and TEM sample preparation. Moreover, Pt-C nanowires are also utilized as intermediate electrical contacts for transport studies of other nano-objects.

It is found that the conductivity increases with thickness for Pt-C (Fernández-Pacheco et al., 2009a) deposits. Particularly, they behave as semiconductors below 50 nm in thickness, whereas they behave as metals for 50 nm in thickness and above (Tao et al., 1990). The metallic content of the deposits is around 33 atomic % and their microstructure consist of 5 nm size fcc phase Pt nanocrystals embedded in an amorphous carbonaceous matrix (De Teresa et al., 2009).

Despite Ga^+ FIB, the growth of Pt-C deposits has been reported using Ne^+ FIB and He^+ FIB (Wu et al., 2013). In the first case, Pt-C Ne^+ FIBID deposits behave as metals (600 $\mu\Omega \text{ cm}$), whereas they behave as semiconductors (180,000 $\mu\Omega \text{ cm}$) using He^+ FIBID. The Pt content in these deposits is around 16 atomic %.

Tungsten

Tungsten-Carbon deposits were grown using tungsten hexacarbonyl, W(CO)_6 , as a precursor, and present a low electrical resistivity at room-temperature 200 $\mu\Omega \text{ cm}$ (Sadki et al., 2004) and improved mechanical properties (Córdoba et al., 2017). Although the main characteristic of these nanostructures is the occurrence of superconductivity at low temperature. Planar and 3D Tungsten-Carbon nanostructures grown by FIBID are detailed explained in Sections 3.1.1 and 3.2, respectively.

Copper

Copper-based deposits were prepared using FIBID with $\text{C}_{10}\text{H}_{13}\text{CuF}_6\text{O}_2\text{Si}$ as precursor. In this respect, semiconducting and metallic deposits were obtained. It is found that its conductivity increases with ion beam current, behaving as metals. Compositional and microstructural studies in these deposits revealed a Cu content of 55 atomic % and Cu crystals embedded in an amorphous carbonaceous matrix (Della Ratta et al., 1993).

Gold

Gold-based deposits were grown using $\text{C}_7\text{H}_7\text{F}_6\text{O}_2\text{Au}$ as precursor. On this basis, semiconducting and metallic deposits were achieved. A high gold content of 75 atomic % allows obtaining metallic deposits with room temperature resistivity around 500 $\mu\Omega \text{ cm}$ (Blauner, 1989; Shedd et al., 1986).

Cobalt

Cobalt-based deposits were fabricated using $\text{Co}_2(\text{CO})_8$ and $\text{Co(CO)}_3\text{NO}$ as precursors, respectively. Electrical studies of these materials revealed their semiconducting and metallic behavior at room temperature. In addition, as-grown (Lapicki et al., 2002a,b) and annealed (Gazzadi et al., 2011) Co-based deposits (50 atomic % Co) behave as ferromagnetic metals with room temperature resistivity of 189 $\mu\Omega \text{ cm}$ and 62 $\mu\Omega \text{ cm}$, respectively. Using He^+ FIB instead of Ga^+ FIB, high resolution and metallic Co 10 nm-wide nanowires were grown with similar room temperature resistivity values (Wu et al., 2014).

Table 1 Material, reference, precursor, ion species, composition, microstructure, electrical behavior and room-temperature resistivity of FIBID nanostructures.

Niobium

Niobium-Carbon is other promising material grown using FEBID with $\text{Nb}(\text{Nme}_2)_3(\text{N-}t\text{-Bu})$ as precursor. It is metallic at room temperature, whereas it presents superconducting properties at low temperature (Porrati et al., 2019) (more details in Section 3.1.1 of this chapter).

Materials grown with FEBID

The applicability of FEBID is also limited to the synthesis of feasible precursors (Swiderek et al., 2018). Precursors used to induce the growth of different materials such as single elements, binary compounds and ternary compounds are briefly discussed in this section.

Single element

The most relevant materials grown with FEBID are listed below.

Platinum

Platinum-Carbon deposits grown using FEBID with $(\text{CH}_3)_3\text{Pt}(\text{C}_6\text{H}_5)_3$ as precursor were the most studied material in the last decade (Botman et al., 2008; De Teresa et al., 2009). The composition and microstructure of deposits consist of 17 atomic % Pt content and 3 nm grain size of face-centered cubic Pt phase crystals embedded in an amorphous carbonaceous matrix, respectively. According to this, its electrical properties studied correspond to a semiconductor behavior.

Tungsten

Tungsten-Carbon deposits present a metal to insulator transition as a function of the W content (Huth et al., 2009). Another interesting feature of these nanostructures is the occurrence of superconductivity at low temperature (Blom et al., 2021; Sengupta et al., 2015). Planar Tungsten-Carbon superconducting deposits grown by FEBID are detailed explained in Section 3.1.2.

Cobalt

Planar metallic and magnetic Cobalt nanostructures using $\text{Co}(\text{CO})_8$ as precursor were fabricated and characterized in the last decade (De Teresa et al., 2016; De Teresa and Córdoba, 2014; Fernández-Pacheco et al., 2009b; Serrano-Ramón et al., 2011). Additionally, the growth of high purity 3D Co nanostructures was also proved (Córdoba et al., 2010, 2016c; Fernández-Pacheco et al., 2013) extending the usage of FEBID for applications in 3D nanomagnetism and spintronics. More recently, 3D nanomagnets grown using FEBID have been key elements to study complex chiral spin states (Sanz-Hernández et al., 2020), magnetoelectrical signals (Meng et al., 2021) and complex textures in the magnetic stray field given by the effect of the curvature, torsion, chirality and magnetic coupling (Donnelly et al., 2021).

Iron

Planar magnetic Iron deposits with Fe content above 75 atomic % were grown using FEBID with $\text{Fe}(\text{CO})_5$ (Gavagnin et al., 2014) and $\text{Fe}_2(\text{CO})_9$ (Córdoba et al., 2012, 2016b; Lavrijsen et al., 2011) precursors. Additionally, 3D magnetic Iron pillars with purity higher than 90 atomic % were also fabricated with $\text{Fe}(\text{CO})_5$ (Gavagnin et al., 2014) and $\text{Fe}_2(\text{CO})_9$ (Córdoba et al., 2016c; Franken et al., 2014; Wolf et al., 2015) precursors.

Gold

Gold based deposits with Au content of up to 72 atomic % were grown using FEBID using $\text{C}_7\text{H}_{10}\text{AuF}_3\text{O}_2$ as a precursor compound (Belić et al., 2017; Koops et al., 1996).

Silver

$\text{AgO}_2\text{Me}_2\text{Bu}$ precursor material has been utilized to direct writing silver nanostructures by FEBID. By selecting the optimized experimental conditions 75 atomic % of silver content in the structures was obtained (Höflich et al., 2017).

Ruthenium

Ruthenium based deposits with Ru content of 23 atomic % were grown using FEBID using $(\eta^3\text{-C}_3\text{H}_5)_3\text{Ru}(\text{CO})_3\text{Br}$ as a precursor (Jurczyk et al., 2019).

Copper

$\text{CuC}_{16}\text{O}_6\text{H}_{26}$ precursor has been used to grow metallic structures by FEBID with copper content of 25 atomic %. A microstructural study revealed deposits consist of copper nanocrystals with sizes of up to 15 nm embedded in a carbonaceous matrix (Haverkamp et al., 2018).

Binary compounds

The possibility of preparing nanostructured binary alloys, which are crucial elements of micro- and nano-electronic devices, with a direct-write technique expands the utilization of this method for many other applications.

On the other hand, the FEBID process allows several precursors to be combined and their flux to be controlled during growth. This ability permits the tuning of the element ratio and the formation of metastable phases of different compounds, which is not feasible using conventional methods for the fabrication of binary alloys.

This is the case for a metastable Pt_2Si_3 phase of binary alloys of Pt-Si (Winhold et al., 2011). By tuning the gas flux of two precursors $(\text{CH}_3)_3\text{CH}_3\text{C}_6\text{H}_4\text{Pt}$ and $\text{Si}(\text{SiH}_3)_4$, binary alloys with specific ratios in platinum and silicon content can be fabricated using the FEBID technique. The minimum resistivity in the prepared alloys was found for a 3:2 Si:Pt ratio.

Furthermore, by adding a magnetic element such as Cobalt, Nickel or Iron to binary alloys, these alloys could include additional functionalities such as magnetism, expanding the use of this technique for applications in nano-magnetism and spintronics.

Binary compounds such as nickel oxide were synthesized by using an in situ two-step process (Córdoba et al., 2016a). As-grown Ni-C nanodeposits grown by FEBID transformed into homogeneous NiO compounds using focused electron beam irradiation under O_2 flux.

In addition, a local synthesis of fluoride compounds, such as cobalt trifluoride phase, was transformed from cobalt nanodeposits, using focused electron beam irradiation under XeF_2 flux (De Teresa et al., 2014).

Specifically, binary CoPt-C alloys consisting of amorphous CoPt nanoparticles embedded in a carbonaceous matrix can be fabricated using FEBID, by combining $\text{C}_2(\text{CO})_8$ and $(\text{CH}_3)_3\text{CH}_3\text{C}_6\text{H}_4\text{Pt}$ precursors (Porrati et al., 2012). These nanoparticles were transformed into face centered tetragonal phase (L1_0) nanocrystals by post-irradiation treatment, which consists of a low-energy electron irradiation process. A transition from a superparamagnetic to a ferromagnetic state has been detected in the alloys at room temperature, allowing their magnetic state to be tuned. The as-grown samples (amorphous nanoparticles) exhibited superparamagnetic behavior evidenced by the lack of hysteresis and coercivity in Hall effect measurements, while the post-irradiated samples (L1_0 phase crystal) exhibited typical ferromagnetic behavior.

In the last decade, another study of binary CoSi-C FEBID alloys produced by simultaneous combination of two homonuclear precursors, $\text{Co}_2(\text{CO})_8$ and $\text{Si}(\text{SiH}_3)_4$, was reported (Porrati et al., 2013). By modifying the precursor flux, the formation of CoSi and CoSi_2 nanocrystals embedded in a carbonaceous matrix was detected in the samples, which allowed the control of their electrical properties from the insulator to quasi-metallic tunneling coupling transition.

In recent years, the investigation of new and feasible heteronuclear precursors for direct-writing functional magnetic nanostructured alloys has been addressed. A first example was reported in 2015, where Porrati et al. (2015) prepared CoFe magnetic nanostructured alloys using $\text{HFeCo}_3(\text{CO})_{12}$ as precursor. Nanowires 50 nm wide had a room temperature resistivity of $43 \mu\Omega \text{ cm}$ and exhibited ferromagnetic behavior. The microstructure of the prepared nanowires consisted of a bcc Co-Fe phase mixed with a spinel oxide FeCo_2O_4 with crystals 5 nm in diameter. More recently, specific binary Co-Si-C alloys have been grown using two new heteronuclear single-gas precursors, CoSi from $\text{H}_3\text{SiCo}(\text{CO})_4$ and Co_2Si from $\text{H}_2\text{Si}(\text{Co}(\text{CO})_4)_2$ (Jungwirth et al., 2021). Both Co_xSi alloys exhibited tunneling magnetoresistance at temperature near room temperature. These two works demonstrated that the use of heteronuclear precursors preserves the initial metal ratio in the prepared magnetic alloys, which encourages going further in the synthesis of more sophisticated precursors for the FEBID and FIBID technology.

Ternary compounds

The fabrication of multilayer nanostructures and even ternary compounds using a direct-writing technique such as FEBID or FIBID could avoid the use of several serial steps typically involved in conventional lithographic preparation. Following this path, Porrati et al. (2017) reported an interesting study in which $\text{Co}_2\text{Fe/Si}$ multilayer nanostructures were fabricated by the alternate FEBID process from $\text{HFeCo}_3(\text{CO})_{12}$ and $\text{Fe}(\text{CO})_5$ precursors to obtain the Co_2Fe compound and Si_5H_{12} precursor to obtain the Si layer. By using low-energy electron irradiation on the multilayers, an intermixing atomic species is induced to obtain ternary nanostructured compounds. Co_2FeSi Heusler alloy is formed for the entire multilayer for thin samples, while in thick multilayers the intermixing occurs mainly at the top of the sample.

Direct-writing of superconducting nanostructures

Planar superconducting nanostructures

FIBID

This section presents a revision of the most significant planar superconducting materials grown using FIBID (Table 2).

Tungsten-Carbon-based materials grown by FIBID using tungsten hexacarbonyl, $\text{W}(\text{CO})_6$, as a precursor, are becoming the most studied FIBID superconductors. Thanks in large part to Sadki's discovery in 2004 (Sadki et al., 2004) that this material behaved as a superconductor below 5.1 K (its electrical resistance decreases from a finite value to zero below its superconducting critical temperature, T_C). The explanation of the huge T_C value in W-C FIBID nanostructures compared to that found for pure crystalline tungsten (15 mK) (Li et al., 2008) remains a matter of debate. Some authors (Córdoba Castillo, 2014; Li et al., 2008; Sadki et al., 2004) relate the high T_C value in nanostructures to their amorphous nature, which is enhanced by the presence of an amorphous

Table 2 Room-temperature resistivity, superconducting critical temperature, composition, and microstructure of planar superconducting FIBID nanostructures.

carbonaceous matrix (from the precursor) and implanted Ga atoms (from the FIB), which presumably amorphize the tungsten atoms. This statement is in good agreement with the high T_C value found in amorphous W-based alloys.

Another interesting feature of these nanostructures is their low electrical resistivity at room-temperature ($\sim 200 \mu\Omega$ cm) that qualifies them to be used as metallic contacts at room-temperature and superconducting contacts below 5 K for electrical transport studies of nano-objects such as nanoparticles, nanowires, nanospheres, etc. and of low-dimensional materials as nano-flakes, nanoribbons, etc.

The various compositional and structural studies of W-C FIBID nanostructures already reported are in agreement with a W atomic content in the 40–50% range, a C atomic content in the 30–40% range and a Ga atomic content in the range of 10–20%, and with their amorphous or short-range order structure. An exception to these values is found in suspended bridges with enhanced mechanical properties and a W atomic content up to 70% (Córdoba et al., 2017).

The W-C FIBID material is considered as a type-II superconductor because an applied magnetic field penetrates the material in a quantized (a flux quantum) and ordered manner (lattice), forming individual superconducting vortices (Guillamón et al., 2008). A superconducting vortex consist of a circular normal core screened by a supercurrent. The circular supercurrents that surround each vortex repel each other arranging them in a triangular Abrikosov lattice. The density of the superconducting vortices in the material increases with the applied magnetic field and the value of that field at which the superconducting state is suppressed is called the upper critical magnetic field (B_{C2}). The B_{C2} in the W-C FIBID material is in the range of 7–8.5 T at 2 K (Córdoba Castillo, 2014; Dai et al., 2013; Sun et al., 2013), while extrapolated to zero temperature it is around 9.5 T (Sadki et al., 2004). Ginzburg-Landau equations predicted two characteristic lengths in a superconductor, the coherence length and the penetration depth, these determined lengths are 6.25 nm and 850 nm, respectively for the W-C FIBID material (Guillamón et al., 2009). By injecting a higher enough external electrical current into the material electrical dissipation occurs due to the unpairing of the Cooper electrons pair. The value of this electrical current is called the critical current (I_C), and the value of the critical current density (J_C) in the W-C FIBID material is in the range of 0.01–0.1 MA/cm² (Córdoba Castillo, 2014; Guillamón et al., 2008; Luxmoore et al., 2007; Sadki et al., 2004; Spoddig et al., 2007). Furthermore, by injecting a current into the material containing a vortex lattice results in an electrical dissipation due to vortex motion within the superconducting regions.

W-C FIBID material can be considered a remarkable system to investigate vortex-related physical phenomena in 2D and 1D structures. In the first case, this material properly follows the microscopic Bardeen–Cooper–Schrieffer (BCS) theory for superconductors (Guillamón et al., 2008). In addition, it is an excellent material to visualize the solid-liquid transition (Guillamón et al., 2009), the order-disorder transition (Guillamón et al., 2014), and the vortex creep phenomenon (Guillamón et al., 2011) in a 2D vortex lattice. In the second case, finite size effects have been investigated in narrow nanostructures (≤ 50 nm in diameter), which are key for their application to superconducting circuits, such as a magnetic field-driven reentrance of the superconductivity caused by vortex confinement (Córdoba et al., 2013), a vortex transfer carried by non-local motion (Córdoba et al., 2019b; Orús et al., 2021a) and an electric field-induced control of superconductivity (Orús et al., 2021b).

Other interesting materials deposited with FIBID exhibited metallic behavior at room temperature, while at low temperature they transitioned to the superconducting state. This is the case for superconducting Niobium-Carbon and Molybdenum-Carbon nanostructures grown using Nb(Nme₂)₃(N-*t*-Bu) and Mo(CO)₆ as precursors respectively. In the first case, Nb-C nanostructures behave as superconductors below 5 K (Porrati et al., 2019). The compositional and structural studies revealed that this material consists of an atomic composition ratio of Nb:C:Ga:N 29:43:15:13, and a polycrystalline microstructure of fcc NbC with a crystal size of 15–20 nm. On the other hand, freestanding 3D NbC nanowires exhibit a broaden superconducting transition between 4 and 11 K. In the second case, Mo-C nanostructures behave as superconductors below 3.8 K (Weirich et al., 2014) with an atomic composition ratio of Mo:C:Ga:O 42:26:26:7.

FEBID

FEBID nanostructures typically contain a lower atomic percentage of metal than those obtained by FIBID, with a few exceptions that are beyond the scope of this chapter. In this way, those materials could be considered less suitable for applications in electronics and so on. Within this scenario, the fabrication of high-quality superconducting nanostructures using FEBID remains a challenge.

In this section, a review of the most significant planar superconducting materials grown with FEBID is presented.

There are currently only two studies of Tungsten-Carbon superconducting materials grown by FEBID using tungsten hexacarbonyl, $W(CO)_6$, as precursor (Sengupta et al., 2015; Blom et al., 2021).

In the first study, the 130 nm wide W-C nanowires behave as superconductors below 2.0 K and their upper critical magnetic field reaches up to 3.7 T. These superconducting parameters are considerably worse than those obtained with FIBID (Section 3.1.1). Although, the compositional and structural studies in W-C FEBID nanowires revealed a W atomic content of 50%, a C atomic content of 40%, and an O atomic content of 10%, and nanocrystalline structure, which are values similar to those obtained in W-C FIBID nanostructures (Sengupta et al., 2015).

In the second study, by increasing the magnitude of the electron beam current by one order (80 nA), the W-C wires 500 nm wide and with an atomic content of 38% W behave as superconductors below 4.5 K (Blom et al., 2021). The T_C value is similar to that obtained in nanowires grown with FIBID (Section 3.1.1). However, since the beam diameter increases with beam current, large beam currents prevent the fabrication of high-quality superconducting nanostructures using FEBID.

Other interesting materials deposited with FEBID exhibited metallic behavior at room temperature, while at low temperature they became superconducting. This is the case for Lead-Carbon and Molybdenum-Carbon superconducting nanostructures grown using $(CH_3CH_2)_4Pb$ and $Mo(CO)_6$ as precursors, respectively.

The 1 μm wide Pb-C structures can be tuned from insulating to metallic behavior (a room-temperature resistivity of 190 $\mu\Omega$ cm) and, in addition, they behave as a low-temperature superconductor with two T_C values. The first $T_C = 7.2$ K coincides with the value of bulk lead, while the second superconducting phase presents a $T_C = 6.2$ – 6.6 K, with an enhanced value of $B_{C2} = 10$ T. Compositional analysis revealed that this material consists of an atomic composition ratio of Pb:C:O 44:31:25 (Winhold et al., 2014).

In the case of Mo-C nanostructures grown by mixing the precursor with H_2O vapor, they exhibit superconducting behavior below ≈ 4 K. Compositional analysis revealed that this material consists of Mo:C 70:30 (Makise et al., 2014).

3D superconducting nanostructures

The exploitation of the third dimension in nano-superconductivity could represent a paradigm shift for the exploration of novel topology- and geometry-induced phenomena (Fomin, 2020, 2018), which do not arise in planar nanostructures (Rezaev et al., 2020), with potential applications in advanced sensing and quantum computing.

In the last years, FIBID is becoming an established route for the direct-writing of 3D superconducting nanoarchitectures, with resolutions down to a few tens of nanometers (Figs. 5 and 6) (Córdoba et al., 2020, 2019a, 2018). The extremely-high resolution of FIBID (Hirt et al., 2017) is the main advantage compared to direct competitors of additive manufacturing methods as two-photon lithography (Seniutinas et al., 2017) and electrodeposition (Bochmann et al., 2018).

Ga^+ FIBID has been used to grow individual 3D superconducting W-C (Li et al., 2012, 2010; Romans et al., 2010) and Nb-C wires (Porrati et al., 2019), with superconducting critical temperature and upper critical magnetic field similar to those obtained for planar nanostructures, semiconducting and insulating 3D materials (Fujii et al., 2005; Matsui et al., 2000; Morita et al., 2003; Nakai et al., 2010), as helices with aspect ratio up to 3 and diameters down to 500 nm (Wang et al., 2019); and arrays of semiconducting and insulating 3D materials (Esposito et al., 2015, 2014). Nevertheless, the resolution in this process is mainly limited by the Ga^+ beam diameter (~ 5 nm) and its high lateral scattering, preventing the growth of sub-100 nm 3D structures by Ga^+ FIBID so far.

A new Gas-FIB source based on lighter and noble-ion elements like He^+ FIB integrated in the helium ion microscope (HIM) (Scipioni et al., 2008) has been particularly successful for the growth of sub-10 nm structures (Wu et al., 2013), due to its small probe size ≈ 0.3 nm, its lower proximity effect (Maas et al., 2010) and higher sensitivity (Sidorkin et al., 2009). The HIM represents an enormous forward step for additive nanolithography method compared to Ga^+ FIBID.

He^+ FIBID has proven to be of importance in the growth of 3D superconducting nanostructures with fancy geometry, higher aspect ratio and outstanding superconducting properties ($T_C \approx 6.2$ – 7.1 K, $B_{C2}(0) \approx 12$ – 15 T), such as hollow nanocylinders (Córdoba et al., 2020, 2018) and nanohelices (Córdoba et al., 2019a).

A noteworthy example of the capabilities of 3D He^+ FIBID is the fabrication of at-will W-C 3D hollow nanocylinders with diameters down to 32 nm and with an aspect ratio of ≈ 200 (Córdoba et al., 2020, 2018) (Fig. 5). The occurrence of a hole of 6 nm in diameter at the center of the standing cylinder is the result of a balance between the milling and deposition regimes. In the particular experimental conditions, the $W(CO)_6$ precursor is decomposed and deposited over the substrate surface and over deposited material in the vicinity of the highly focused He^+ beam spot, while simultaneously is sputtered by He^+ FIB milling at the center of the beam spot, creating a hollow nanocylinder with a wall thicknesses down to 13 nm. The critical temperature of the W-C 3D hollow nanocylinder is 6.2 K, which is up to 1.5 times higher than that obtained in Ga^+ FIBID W-C nanostructures of similar dimensions. TEM-based characterization studies indicate a higher amount of W in the 3D nanostructures than those grown by Ga^+ FIBID, up to 70% of W in atomic content; and the presence of 20–30 nm-sized crystalline grains of the fcc WC_{1-x} phase, that it is close to the value of the nanowire diameter. Additionally, the determined coherence length and the penetration depth in this 3D nanostructures are 5 and 850 nm respectively.

Another remarkable example of 3D He^+ FIBID is the patterning of W-C 3D nanohelices with at-will geometries by tuning some key deposition parameters (Córdoba et al., 2019a) (Fig. 6). Córdoba et al. reported the smallest and more-densely-packed superconducting nanohelix ever grown so far, as small as 100 nm in diameter, and with an aspect ratio of 65. These nanohelices become superconducting at 7 K and show a large upper critical magnetic field and critical current density.

In addition, given its helical 3D geometry (i.e., curvature and torsion), fingerprints of vortex and phase-slip patterns determined by topologically non-trivial screening currents and confinement potentials are experimentally identified with resistance steps in their current–voltage curves and supported by numerical simulations based on the time-dependent Ginzburg–Landau equation (Fig. 6). The preparation of 3D helical nanoarchitectures could impulse the extension of vortex matter (Wördenweber, 2017) toward 3D curvilinear chiral geometries, whose experimental and theoretical investigations represent an essentially novel research direction in Abrikosov fluxonics (Dobrovolskiy, 2017).

These outstanding examples have opened a conceptually novel route for the fabrication of advanced nano-superconductors, which is unachievable with other additive manufacturing techniques, putting focused ion beam techniques at cutting-edge of the frontier of knowledge in creating 3D nano-superconductors. Although, it is fair to mention that they are still limited in ability to create a variety of 3D complex architectures and superconducting materials. Therefore, in order to exploit the potential of moving toward to three dimensions, some significant experimental challenges associated with the fabrication and characterization of complex 3D nanoscale geometries and topological configurations have to be addressed.

Applications to superconducting devices

Planar superconducting nanostructures

Basset et al. has demonstrated that planar W-C FIBID nanostructures exhibit appealing properties such as high kinetic inductance, which is an important requirement for their implementation in high-frequency superconducting circuits (Basset et al., 2019). These circuits could be very interesting to investigate mesoscopic systems where the spin degree of freedom needs to be addressed. Therefore, in this work the high performance of these hybrid *microwave resonators* with a strong non-linear response was evaluated by combining Nb thin films grown by sputtering technique with 35–75 nm-wide W-C nanowires grown with He^+ FIBID.

Fig. 6 3D W-C superconducting nanohelices grown by He^+ -FIBID. (a), (b) SEM images of nanohelices of types 1 and 4 (52° tilted stage). Inset in (a) shows the top view of the nanohelix (measured bar = 100 nm). (c) Normalized resistance as a function of temperature for nanohelix of type 1. Inset shows the SEM image for the nanohelix of type 1 connected for magnetotransport measurements. (d) Experimental Resistance-Current measurement for the nanohelix of type 6. Inset shows the SEM image for this nanohelix. (e) Simulated order parameter distributions plotted over the 2D surface of the helical structure of type 6 for the magnetic field 2 T. Remarkably, ultra-fast vortex motion was recently shown for Nb-C microwires grown with Ga^+ FIBID (Dobrovolskiy et al., 2020) providing an opportunity to investigate non-equilibrium superconducting systems. Furthermore, the weak vortex pinning, the critical current near the depairing current, and the fast heat removal from heated electrons allow one to consider this material as a suitable candidate for *fast single-photon detectors*.

Another recently highlighted application for W-C superconducting structures is the fabrication of *Josephson Junctions* in a single-step process using FEBID (Blom et al., 2021). Josephson coupling in these devices is revealed by the Shapiro step response for various microwave frequencies and electrical magneto-transport measurements. This approach provides an available method to fabricate highly-sensitivity detectors such as superconducting quantum interference devices (SQUIDs) and single-photon detectors at a predefined place.

Recently, Orús et al. presented an experimental demonstration of the modulation of the critical current in planar superconducting 45 nm-wide, 2.7 μm -long W-C FIBID nanowires using a side-gate voltage (Orús et al., 2021b). The phenomenon in which the superconductivity of a nano-superconductor can be suppressed by applying an electric field in its vicinity has already been observed in other superconducting materials (Bours et al., 2020; De Simoni et al., 2020, 2018a; Paolucci et al., 2019; Puglia et al., 2020; Rocci et al., 2021, 2020), and at the present time its microscopic explanation, which cannot be accounted for by means of the Barden-Cooper-Schrieffer theory of superconductivity only, has proven elusive and challenging and represents a matter of debate (Alegria et al., 2021; Chirolli et al., 2021; Golokolenov et al., 2021; Mercaldo et al., 2020; Puglia et al., 2022, 2021; Ritter et al., 2022, 2021; Solinas et al., 2021; Virtanen et al., 2019).

The prepared *W-C Superconducting Field Effect Transistor (S-FET)* nanodevices present comparable figures of merit to those retrieved in superconducting nanostructures (Ti, Nb, Al, V, NbN) grown using electron beam lithography. In particular, they exhibit a higher critical temperature and a lower critical gate voltage value needed to suppress superconductivity than most of the other superconductors. This modulation of the critical current is accounted for by its squeezing by the electric field within a theoretical model based on the Ginzburg-Landau equation which includes boundary conditions in the nanostructure, and adequately reproduces the experimental data.

This work provides with valuable insight in the present effervescent discussion on this puzzling phenomenon, and also presents FIBID as a powerful technique providing with enhanced patterning flexibility and not requiring the use of resists and solvents. This technique could be exploited for the fabrication of complex functional nanodevices (Paolucci et al., 2019, 2018), such as novel types of Josephson junctions (De Simoni et al., 2018b), logic gates (Lee et al., 2003), and single-photon detectors (Kadin and Johnson, 1996).

3D superconducting nanostructures

Currently, fabrication and characterization of 3D nano-superconductors remain a challenge. This is mainly due to the lack of nanofabrication techniques capable of growing these nano-superconductors with characteristic sizes in the order of magnitude of the superconducting coherence length. In this scenario, advanced lithography techniques such as those based on focused ion beams (FIB) and focused electron beams (FEB) can be utilized. Actually, 3D FIBID prototypes are adequate for investigating new concepts in the field of 3D nano-superconductivity as already mentioned in the Section 3.2 of this chapter.

In particular, nanohelix arrays can be considered *superconducting metamaterials* (Anlage, 2011) whose microwave response could be controlled by selecting the contact points of individual nanohelices for voltage-current measurements (Córdoba et al., 2019a), as detected in planar nano-superconductors (Dobrovolskiy et al., 2015). Furthermore, a fine adjustment of the shape of the nanohelices allows one to expect commensurability effects in the presence of moderate high magnetic fields (Córdoba et al., 2013; Dobrovolskiy et al., 2018) that can be considered as one more degree of freedom for the response of the 3D nano-superconductor.

Conclusion

In this chapter, we have described an advanced method for direct-writing of nanostructures in all three dimensions using focused ion and electron beams. Depending on the precursor utilized, these materials can harbor a wide range of electronic properties, from insulators to superconductors. In particular, some examples of superconducting nanostructures created by these techniques have been widely discussed, with special interest in the case of 3D nano-superconductors which can host rich and novel physical phenomena due to geometric- and topological-induced effects. These advanced nano-superconductors could be considered building blocks for applications in superconducting electronics (Makarov et al., 2022), such as magnonics, fluxonics, quantum computing, electric field-induced control of superconductivity, ultra-high sensitivity sensors and lots of others.

The future of FIBID and FEBID as a well-established additive nano-manufacturing technology largely depends on the enormous efforts in the improvement of instruments and techniques to overcome several of their current limiting factors (Hirt et al., 2017). Some of them are outlined below:

- Scalability: the reproducibility of sequential nanostructures is limited to an array size of a few tens of microns mainly due to beam proximity effects and a non-stationary state of the precursor flux (Esposito et al., 2015, 2014).
- Throughput: the throughput of FIBID and FEBID is rather limited because the process is performed only with a single beam sequentially scanning one spot after another. Direct-writing of very large areas requires high processing times and moreover, beam and precursor flux instabilities must be addressed. The development of different ion sources, with small probe sizes and capable of providing sufficiently high current densities (Bassim et al., 2014; Smith et al., 2014) could increase the throughput of the technique and thus facilitate overcoming this critical limitation.
- Reproducibility: complete control of experimental conditions in the FIBID and FEBID processes is the only way to obtain advanced nanostructures with high reproducibility and to adjust their physical and chemical properties. The integration of a laser interferometer platform in the equipment could be considered one of the steps forward to achieve this goal (Bauerdick et al., 2013; Hentschel et al., 2020).
- Software: hybrid Monte Carlo– continuum simulations of FIBID and FEBID together with computer-aided design programs (Deinhart et al., 2021; Fowlkes et al., 2018; Keller and Huth, 2018; Skoric et al., 2020), which predict proximity effects and gas flux issues, could be adapted and improved for larger area nanofabrication.

The limiting factors mentioned above, of course, must be widely considered for the fabrication of 3D nanostructures. Particularly, the recent experimental achievements in the nanofabrication and characterization of 3D nano-superconductors together with the theoretical predictions (Section 3.2 of this chapter), surely arouse great interest in addressing more extensive studies on this subject in the coming years. For example, the ability to create chiral nanostructures enables fine tuning of the properties and place of topological states, providing an enhanced functionality for future metamaterials and devices. In this way, FIBID and FEBID could become cutting-edge additive nano-manufacturing techniques to open a conceptually novel route for the fabrication of advanced nanoarchitectures based on complex 3D geometries to allow their integration into multi-functional circuits, in highly topical fields such as sensing and electronics, what is not feasible with other additive manufacturing techniques.

We expect that this chapter encourages additional investigations in 3D nanoprinting applied to nano-superconductivity, and promotes win-win situations by addressing geometrical- and topological-induced effects in live and molecular science as well as soft and condensed matter.

Abstract

Inhomogeneities in the orientation, composition, and configuration of the atomic structure of a solid collectively make up what is referred to as the internal structure or microstructure. The term macrostructure is sometimes used to refer to the largest components of the internal structure. In this article, the microstructures of inorganic materials are surveyed, identifying important components of each type of microstructure. Throughout, attention is given to the mechanisms by which microstructures form during materials processing.

Key points

- Microstructures are defined by the shapes, sizes, and orientations of the individual crystals contained within the macrostructure, as well as the configuration of grain boundaries and interfaces that connect them.
- The microstructure is inherited from the materials processing conditions and very different microstructures are formed by sintering, solidification, vapor deposition, recrystallization, and phase transformation.
- The energies of the grain boundaries and interfaces within the microstructure provide the driving force for microstructure evolution during thermal processing.

Introduction

A crystalline solid is made up of indistinguishable groups of atoms positioned at the sites of a Bravais lattice. If the atomic structure is approximately uniform in both orientation and composition throughout the solid, the material is referred to as a single crystal. When the atomic structure is not uniform, it is known as a polycrystal. In this second and more common instance, the irregularities in the orientation, composition, and configuration of the atomic structure collectively make up what is referred to as the internal structure or microstructure. The term macrostructure is sometimes used to refer to the largest components of the internal structure. Within this article, all components of the internal structure will be referred to as the microstructure.

Polycrystals can be thought of as aggregates of much smaller crystals joined together by a network of internal interfaces, as illustrated schematically in Fig. 1. Within the aggregate, the individual crystals are referred to as grains. The interface that separates two grains of the same composition, but different lattice orientation, is called a grain boundary and the interface that separates two grains with different compositions is called a phase boundary. The granular nature of polycrystalline matter has been recognized since at least 1775 when Grignon sketched grains observed on the surface of a piece of fractured wrought iron. This first recorded observation points to an important feature of the interfaces within the microstructure: they are frequently points of internal weakness along which failure, by fracture or corrosion, propagates through the interfacial network. During the last century, microstructural studies have flourished amid the realization that many of the macroscopic properties of polycrystalline solids are

[☆]*Change History:* March 2023. All changes made by Gregory S. Rohrer. Figures 16, 17, and 28 were updated. Sections Grain boundaries in single phase microstructures and Duplex microstructures by transformation in the solid phase were updated.

Fig. 1 Schematic illustration of a polycrystalline solid, with black dots representing points on the lattice and gray lines denoting boundaries between grains with different orientations.

strongly influenced by the internal structure. While these studies established the solid foundation of knowledge that will be reviewed in this article, it should also be recognized that there are many unresolved questions about microstructural genesis and the microstructure-property link that continue to be actively researched. In general terms, one can say that polycrystalline microstructures result from crystal nucleation, growth, and capillarity driven morphological changes that lead to a reduction in the interfacial energy. In this article, the basic principles behind these processes will be described and examples of prototypical microstructures will be presented. The article will focus on dense, inorganic, polycrystalline microstructures that occur in man-made materials. Single phase microstructures are discussed first and multiphased structures are described in the second section.

Single phase microstructures

The term single phase polycrystal is used to describe an aggregate of crystals that is uniform in its atomic structure and composition. Throughout a single-phase microstructure, it is only the orientation of the Bravais lattice within the individual grains that differs. The defining elements of the microstructure are the distribution of crystal sizes, the distribution of crystal shapes, the distribution of crystal orientations, and the types of grain boundaries between the crystals. Single phase microstructures can be formed by sintering a solid powder, by crystallizing a precursing liquid, gaseous, or amorphous phase, or by recrystallizing a deformed precursor. Microstructures resulting from each of these states are described briefly below.

Single phase microstructures by sintering

The excess free energy per unit area of a grain boundary (γ) can be thought of as the energy to create equal areas of the two free surfaces on either side of the boundary, minus a binding energy associated with the formation of bonds across the interface as the surfaces are joined. Therefore, if there is bonding across the interface, it is energetically preferable to replace two free surfaces with a grain boundary of the same area. This is the driving force for the process of sintering, in which individual crystalline particles change shape and bond with one another to form a dense polycrystal. Further heating after complete densification leads to grain growth, an increase in the average grain size. This too is a capillarity driven process, because as the average grain size increases, the total grain boundary area (and its associated energy) decreases. If the grain boundary energy and mobility are not too anisotropic, then an equiaxed microstructure develops. In other words, each grain has approximately the same dimensions in all directions. An equiaxed microstructure is illustrated in Fig. 2.

The shapes of the grains are determined in part by the relative rates at which the crystal grows in different directions (a kinetic effect), and in part by the requirement that the interfacial forces balance at their points of intersection (an equilibrium effect). The equilibrium equation for the point where three interfaces meet is known as the Herring condition (Herring, 1953):

Fig. 2 Montage of scanning electron microscope (SEM) images of spinel, MgAl_2O_4 . The contrast at the grain boundaries results from thermal grooving.

Fig. 3 Schematic of the triple line (l) along which three interfaces meet, defining the terms in the Herring equation.

$$\sum_{i=1 \text{ to } 3} \gamma_i \hat{t}_i + \frac{\partial \gamma_i}{\partial \beta_i} \hat{n}_i = 0$$

The terms in this expression are described in Fig. 3. Under the condition that the energy does not depend on orientation, this reduces to the more familiar Young equation,

$$\frac{\gamma_1}{\sin \Psi_1} = \frac{\gamma_2}{\sin \Psi_2} = \frac{\gamma_3}{\sin \Psi_3}$$

where the Ψ_i are the dihedral angles in Fig. 3. If the energies of all the interfaces are assumed to be equal, then the dihedral angles are 120° . If this is the case, then dihedral angles at quadrjunctions where four triple lines intersect must be 109.5° . To meet these conditions and fill space, some curvature must be introduced in the boundaries and this creates a driving force for motion. If the grain boundary energies are isotropic, boundaries move toward their center of curvature to reduce their total area. The situation was considered in two-dimensions by von Neumann and Mullins (Mullins, 1956), who showed that if equilibrium dihedral angles are to be maintained in an isotropic structure, then grains with more than six sides will always grow and grains with fewer than six sides will shrink (see Fig. 4). While the problem is not easily solved in three dimensions, it is currently thought that grains with 13 or fewer faces shrink while those with 14 or more grow. Recent three-dimensional studies suggest that the number of grain sides does not provide a reliable prediction of whether a grain will grow or shrink (Bhattacharya et al., 2019). In a variety of studies, the average number of faces per grain has been measured to be between 12 and 14. A sketch of a typical grain is shown in Fig. 5.

Fig. 4 Schematic showing the configurations of boundaries in a two dimensional system under the assumption that the grain boundary energy is isotropic. In this case, the boundaries must always meet with 120° dihedral angles. This means that if a grain has fewer than six sides, the boundaries are convex and will move inward (a and b), if it has exactly six sides there is no curvature and the boundaries are stationary (c) and if it has more than six sides (d) the boundaries are concave and move outward.

Fig. 5 A schematic showing the three dimensional shape of a grain within a polycrystal. The black lines are edges on the front of the grain and the gray lines are edges on the back of the grain.

Kinetic grain growth theories generally predict that the average grain size increases with the square root of time (t) so that the average radius, $\langle r \rangle$, is:

$$\langle r \rangle = (Kt)^n$$

Where K is a positive constant and n , the grain growth exponent, is ideally equal to $1/2$. Furthermore, after the effects of the initial grain size distribution have disappeared, there is a steady state distribution of grain sizes that is scale invariant. The form of the distribution, originally derived by Hillert (Hillert, 1965), has a maximum grain size that is about $3/2$ times the average size:

$$P_H(\rho) = (2e)^3 \frac{3\rho}{(2-\rho)^5} \exp[-6/(2-\rho)]$$

In this equation, $\rho = r/r^*$, where r^* is the critical radius; grains smaller than r^* shrink while grains larger than r^* grow. The distribution is plotted in Fig. 6. In practice, observed grain growth exponents are usually less than $1/2$, the maximum grain size

Fig. 6 Grain size distributions. The most commonly observed distribution of grain sizes is lognormal (P_L) while the theory of capillary driven grain growth predicts a different distribution (P_H). A schematic of a bimodal distribution is shown in the lower part of the figure.

greatly exceeds $3/2$ times the average, and the distribution of grain sizes is most frequently reported to be lognormal, where the number of grains with dimensionless size ρ is:

$$P_L(\rho) = \frac{1}{\sqrt{2\pi}\sigma} \frac{1}{\rho r^*} \exp \left[-(\ln \rho)^2 / 2\sigma^2 \right]$$

In this expression, σ is the width of the distribution. Microstructures that exhibit unimodal and roughly lognormal distributions of grain sizes are usually called normal. However, in some cases the distribution of grain sizes is bimodal (see Fig. 6 for comparison to normal distributions) and such distributions are said to be the result of abnormal growth. An example of a microstructure with an abnormal distribution of grain sizes is illustrated in Fig. 7.

When the anisotropy in the grain boundary energy and mobility is large, the grains adopt distinct shapes and are frequently bounded by flat interfaces, indicating that the orientation corresponds to a cusp or singularity in the function that describes the

Fig. 7 Visible light micrograph showing the microstructure of a polycrystalline BaTiO_3 specimen. Parts of two grains on the left are much larger than the cluster of average grains on the right. The regular patterns within each grain are twin plates that formed by a martensitic transformation during cooling.

Messing and Matthew M. Seabaugh, Department of Materials Science and Engineering, Pennsylvania State University.

orientation dependence of the grain boundary energy. For example, the microstructure in Fig. 8 shows a section through randomly oriented plate-like grains. Depending on the processing, the shapes may also exhibit preferred orientation or texture, as illustrated in Fig. 9. In this case, the $[0001]$ axes of the rhombohedral lattice of Al_2O_3 are oriented in the vertical direction. The general phenomena of nonrandom distributions of crystal orientations with respect to the external reference frame, as illustrated in Fig. 9, is referred to as texture.

Single phase microstructures by crystallization

When a microstructure forms by crystallization from a liquid, gas, or amorphous matrix, crystal nucleation requires the formation of an interface between the crystalline and noncrystalline phase. Assuming the interface energy (γ_s) is isotropic and that the change in free energy per volume upon crystallization is ΔG_v , then the free energy change for the formation of a nucleus with radius r is given by

$$\Delta G(r) = 4\pi r^2 \gamma_s - \frac{4}{3}\pi r^3 \Delta G_v$$

As illustrated in Fig. 10, the change in the free energy as a function r is initially positive. Only after a critical size is reached will further growth stabilize the crystal. Thus, there is an energy barrier, ΔG^* , that inhibits homogeneous nucleation. If a heterogeneous surface is present (for example, the mold walls of a casting system or a substrate in a vapor deposition system), and there almost always is,

Fig. 10 Plot of the free energy change as a function of nucleus radius. The change is initially positive. Additional growth reduces the energy only beyond a critical size. For heterogeneous nucleation, the barrier is lower.

then we must consider not only the creation of the surface dividing the nucleus from the surrounding liquid or gas, but also the elimination of the heterogeneous surface and the creation of the interface between the nucleus and the heterogeneous surface. Using the Young equation, the relationship between the various interface energies can be expressed as a contact angle, θ , in the following way:

$$\cos\theta = \frac{(\gamma_h - \gamma_{sh})}{\gamma_s}$$

The terms in the equation above are defined in the Fig. 10, assuming the crystallization of a spherical cap on the heterogeneous surface. With this parameter, the free energy change for heterogeneous nucleation can be written in a form similar to that for homogeneous nucleation:

$$\Delta G(r) = \left[4\pi r^2 \gamma_s - \frac{4}{3}\pi r^3 \Delta G_V \right] S(\theta)$$

Where the shape factor is $S(\theta) = (2 + \cos\theta)(1 - \cos\theta)^2/4$. Because this term is always less than unity, the free energy change for heterogeneous nucleation is always less than that for homogeneous nucleation. Thus, crystal formation always initiates from a heterogeneity and most frequently from the walls of the container or a deliberately introduced substrate. This leads to so-called columnar microstructures, such as those illustrated in Figs. 11 and 12. The microstructure in Fig. 11 results from nucleation and growth from the walls of a mold in a casting and the microstructure in 12 results from the deposition of a vapor on a substrate. It should be recognized that heterogeneous nucleation can be initiated in a more or less uniform manner by introducing a finely dispersed heterogeneity and this can lead to a equiaxed microstructure. Uniform heterogeneous nucleation can also occur when a material is recrystallized from a deformed matrix.

Grain boundaries in single phase microstructures

The complexity of the grain boundary networks within polycrystals arises from the number of crystallographic degrees of freedom. Three parameters are required to describe the lattice misorientation between two crystals and two additional parameters are required to describe the orientation of the grain boundary plane. The number of distinguishable boundary types in this five-dimensional parameter space is large. For example, in a cubic material, if the five parameters are measured with 5° of resolution, then there are 5×10^4 distinguishable types of grain boundaries (Rohrer et al., 2004). In general, the distribution of grain boundary surface area is not uniform over the five parameters. Textures have been measured both in the space of lattice misorientations and grain boundary orientations. For example, Fig. 13 shows the distribution of lattice misorientations in WC, showing that boundaries with a 30° misorientation about $[0001]$ and a 90° misorientation about occur with a higher and random frequency. These data are plotted without regard for the particular boundary plane. In Fig. 14, the distribution of grain boundary plane area is shown for the two highly populated misorientations identified in Fig. 13. These data demonstrate that hexagonal WC has a preference for grain boundary planes terminated on $\{0001\}$ and $\{10\bar{1}0\}$ surfaces (Kim et al., 2008).

The origin of texture in the space of grain boundary types depends on the origin of the microstructure. In the case that the microstructure results from normal grain growth, grain boundary texture results from the anisotropy of the grain boundary energy. It has been reported that in many materials, low energy grain boundaries are observed more frequently than higher energy grain boundaries. Three-dimensional microstructure data (obtained by serial sectioning or x-ray microscopy) can be used to determine the anisotropy of the grain boundary energy as a function of all five grain boundary parameters. The process involves measuring the geometry and crystallography of all of the triple lines in the microstructure and finding the optimized set of energies that satisfy the Herring equation (Shen et al., 2019). In addition to the grain boundary energy, it is also possible to measure the grain boundary curvature and the grain boundary velocity as a function of all five grain boundary parameters. While curvature and velocity are linearly related in bicrystals, no similar relation has been found in polycrystals (Bhattacharya et al., 2021). The mechanisms that cause grain boundary texture in microstructures formed by transformation or recrystallization are still being explored.

In cubic close packed metals, twins commonly form during recrystallization. In general, a twin is any grain boundary with a mirror in the grain boundary plane. In cubic close packed metals, the most common twin is a grain boundary with a misorientation

Fig. 13 The grain boundary character distribution in WC, plotted in axis-angle space. The entire range of distinguishable misorientation axes in the hexagonal system is represented in each triangle, and the individual triangles represent different rotations about these axes. The units are in multiples of a random distribution (MRD).

Fig. 14 The distribution of grain boundary planes at two specific misorientations: (a) for 90° rotations about the axis and (b) 30° about the $[0001]$ axis. The hexagon marks to position of the $[0001]$ axis and the rectangle the position of the $[1000]$ axis. The positions of the peaks indicate that for both types of grain boundaries, the pure twist configuration is preferred.

Fig. 15 Image quality electron backscattered pattern map of alpha brass. The black lines indicate the positions of grain boundaries. The straight boundaries are twins. Micrograph courtesy of Valerie Randle, University of Wales, Swansea.

of 60° about $[111]$ on the (111) plane. An example of a highly twinned alpha brass microstructure is illustrated in Fig. 15. In lower symmetry materials, if the crystal structure has only small deviations from the ideal cubic structure, then mosaic twinning is common. A twinned WO_3 microstructure is illustrated in Fig. 16. The crystal structure deviates slightly from the ideal cubic perovskite structure and the primary domains have misorientations of $\approx 90^\circ$ around the $[100]$ axis and are on $\{110\}$ grain boundary planes, where the indices refer to the cubic perovskite structure.

Grain boundaries are often classified according to their inverse lattice coincidence number (Σ), where a low Σ number signifies high coincidence. It has been common in the literature to assume that grain boundaries with a low Σ have a low energy. However, there is no evidence to suggest that this is true. In fact, the largest surveys of grain boundary energies conducted by atomistic modeling and by experiment indicate no relationship between the inverse coincidence number and energy, as illustrated in Fig. 17 (Ratanaphan et al., 2015). The data in Fig. 17 illustrate that grain boundaries with the same value of Σ can have a wide range of energies and that some low energy grain boundaries have large values of Σ .

It has been found that certain properties of cubic close packed materials are improved by increasing the fraction of $\Sigma 3$ boundaries. Because of crystallographic constraints at grain boundary triple lines, this also increases the fraction of $\Sigma 9$ and $\Sigma 27$ boundaries; the three grain boundary types are collectively referred to as $\Sigma 3^n$ boundaries. The process referred to as grain boundary engineering, which usually involves repeated cycles of mild deformation followed by recrystallization, has been used to increase the fraction of $\Sigma 3^n$ boundaries in cubic close packed materials with low to medium stacking fault energies such as Cu, Ni, and Pb.

Fig. 16 Backscatter electron contrast image of γ - WO_3 . The contrast results from domains formed when the crystal transformed from a higher symmetry phase to a lower symmetry phase during cooling.

Fig. 17 Energies of 408 grain boundaries in Fe calculated by the embedded atom method and plotted as a function of their inverse coincidence (Σ number).

The micrograph in Fig. 15, discussed above, shows an example of a grain boundary engineered microstructure in which approximately 45% of the boundaries are of the type $\Sigma 3^n$. As these boundaries increase in concentration, they break up percolating clusters of general boundaries that are more susceptible to failure.

Duplex microstructures

Duplex microstructures contain two distinct phases, which are materials that can be distinguished by their structure or composition. In principle, a microstructure may contain many different phases, but the discussion here is limited to the case of two phases. The defining elements of the two-phase microstructure are the same as in the single-phase microstructure, only it is also necessary characterize the configuration of the two phases and the volume fractions. As in the single-phase microstructures, the configuration is determined both by equilibrium phenomena and kinetic phenomena. Because of the added complexity, there are a wider range of possibilities. Selected cases are discussed in the following sections.

Duplex microstructures formed by consolidation

The most direct method to create a duplex microstructure is to physically mix the two phases and then consolidate the mixture by sintering. The degree to which the two phases wet each other strongly influences the configuration. Referring once again to the

Fig. 18 Schematic of the interfacial equilibrium at the point where phase B meets three grains of phase A. The dihedral angle, Ψ , is a measure the relative interfacial energies.

Fig. 19 Montage of topographic AFM images of a WC/Co surface. The surface was etched in such a way that the WC crystals were attacked preferentially, and they appear as the darker contrast. The Co matrix has the lightest contrast.

Young equation, the equilibrium geometry at the points where the phases meet is a function of the interfacial energies. If we label the phases A and B, and assume that their interface energies are isotropic, then the dihedral angle between the two AB interfaces (see Fig. 18) is given by:

$$\cos(\Psi) = \gamma_{AA}/2\gamma_{AB}$$

Note that when $2\gamma_{AB} \ll \gamma_{AA}$, the dihedral angle goes to zero and in this case the two phases completely wet each other. As γ_{AB} approached γ_{AA} , the two phases become increasing non-wetting and the dihedral angle increases toward 180° . Two examples are shown in Figs. 19 and 20. In Fig. 19, Co, which is liquid at the processing temperature, completely wets the angular WC crystals. In this case, the WC crystals occupy 90% of the volume and form an interconnected, skeletal network. The aluminum oxide - tanatalum oxide mixture in Fig. 20 provides an example of a non-wetting combination. The dark grains are the Al-rich phase which poorly wets the Ta_2O_5 boundaries.

Duplex microstructures by solidification

When microstructures form by the solidification of a homogeneous liquid, the phases are not as uniformly dispersed as when formed by a physical mixture followed by consolidation. Interestingly, well defined patterns can develop under these conditions.

Fig. 21 (a) A dendrite observed on the surface an Al-4.5 wt% Cu casting. (b) A section through the same casting, illustrating the appearance of random sections through the network of Al dendrites. The dark contrast is the Cu rich phase.

When a single phase liquid is crystallized in a two phase region where a solid and liquid phase coexist, one of the most common morphological patterns to develop is the dendrite, or branched structure, as illustrated by the microstructures in Figs. 21 and 22. It should be noted that while dendrites can also form during the solidification of a pure material into a supercooled liquid, this situation is far less common than that of the binary alloy. For the single-phase case, one can imagine that protrusions in the growth front can be stabilized if the liquid is supercooled and the latent heat of crystallization is extracted through the solid. In this case, heat is removed more efficiently from the tip of the protrusion that juts out into the supercooled fluid than it is from the valleys between protrusions.

To describe the mechanism by which dendrites form in a binary alloy, consider the simple binary eutectic phase diagram illustrated in Fig. 23. For an alloy with composition C at a temperature less than T_L , there is a range of temperature where the solid and liquid coexist, but with different compositions. The solid alloy α has composition C_α and always contains less B than the liquid, with composition C_L . In fact, one can say that the solid is always relatively more pure than the liquid from which it crystallizes. This means that as the crystal grows, the liquid at the interface is relatively enriched in B and that the enriched liquid freezes at a lower temperature, specified by the liquidus line in Fig. 23. Therefore, a protrusion in the interface can be stabilized because it juts into a relatively more pure liquid (see Fig. 24). In the valleys between protrusions, on the other hand, the liquid rich in B is trapped between opposing growth fronts. Thus, the growth front at the tip of the protrusion is in contact with a liquid that freezes at a higher temperature than the liquid in the valleys between the protrusions. This causes the tip to grow faster than the lateral surfaces and the result is cellular or, more commonly, a dendritic morphology.

Dravid, Department of Materials Science and Engineering, Northwestern University.

Fig. 26 Schematic of the growth of a lamellar microstructure maintaining a nearly planar growth front.

When the remaining liquid cools to the temperature T_E , two solid phases (α and β) crystallize directly from the liquid. This most frequently results in a lamellar microstructure, such as those shown in Fig. 25, where the two phases have alternating bands of dark and light contrast. Because both solids are in equilibrium with the same liquid, but themselves have very different compositions, they must simultaneously reject solute to feed the growth of the other phase. In other words, as a layer of the α phase grows, it must reject solute (B) laterally to supply neighboring lamella of the β phase. As the β phase crystallizes, it rejects A, which sustains the growth of the α phase. This cooperative process, schematically illustrated in Fig. 26, stabilizes a nearly planar growth front.

In most solidification processes, cooling will take the materials through a region of solid-liquid coexistence, in which a dendritic structure will grow. When the remaining liquid reaches the eutectic temperature, it will solidify in a lamellar microstructure, leading to a mixed microstructure. In general, this situation is not an equilibrium configuration. Annealing at a temperature just below the eutectic will cause the compositional concentration gradients to homogenize and the morphologies of the crystals to spheroidize and become more equiaxed.

Duplex microstructures by transformation in the solid phase

Duplex microstructures can also form by transformation in the solid phase. As an example, consider the rapid cooling of α on the phase diagram in Fig. 23, from T_s to T_{ss} . At T_{ss} , the supersaturated α phase will decompose to $\alpha + \beta$, and this will happen entirely in the solid state. As with solidification, the characteristics of the microstructure that develop are determined by the nucleation and growth of the phase. The free energy change during the nucleation process is similar to that for heterogeneous nucleation, except

that an additional term must be added to account for the volumetric strain energy associated with any expansion or contraction that might accompany the transformation. The disposition and shape of this phase depends on the structural relationship between the parent and child phases, features preexisting in the microstructure that serve as heterogeneous nucleation sites, the degree of supersaturation during the nucleation and growth of the phase, and the mechanism of the transformation. Because of all of these parameters, there are a wide range of possible microstructures that can form and only a few of characteristic examples are described in the remainder of this article.

Precipitation from a supersaturated solid solution requires the long range diffusion of solute to the site of growth. For this reason, the distribution of a precipitated phase will depend in the degree of undercooling or supersaturation. When large, the driving force for the precipitation reaction is amplified and atomic mobility is limited. This leads of a uniform distribution of very small precipitates. For example, the microstructure in Fig. 27 shows cuboidal γ' precipitates in a $\text{Ni}_{70}\text{Cr}_{20}\text{Al}_{10}$ superalloy. In this case, the structure of precipitating phase differs little from that of the parent phase, so there is an orientation relationship between the two. In cases where the kinetics for transport are higher and the supersaturation is not as large, precipitates will nucleate at heterogeneities such as grain boundaries.

The formation of lamellar microstructures from the solidification of a eutectic has already been described. In the case of the eutectoid reaction, where a single solid phase decomposes to two new solid phases, the microstructure that is formed is similar to that formed by the eutectic reaction, but the lamellar phase typically nucleates and grows from the grain boundaries. Similar microstructures can also be generated by the cellular transformation from a supersaturated solid solution.

There are also solid to solid transformations that do not require long range diffusion and these processes also lead to distinct microstructures. In the massive transformation, a single phase decomposes to one or more phases that have the same composition, but different crystal structures. Because it is not necessary to alter the composition, the interface can move very rapidly. The massive transformation frequently nucleates at grain boundaries and the rapid interface motion leaves an irregularly shaped precipitate.

Martensitic transformations are diffusionless processes by which a material changes crystal structure without requiring any of the atoms to change position by more than a lattice spacing. Typically, the parent and child structure are related by a shear deformation process. In the resulting microstructure, lens shaped precipitates grow quickly to the size of the grains of the parent phase, creating the characteristic microstructure, such as the one illustrated in Fig. 28. The fully martensitic microstructure in Fig. 28 formed by quenching a steel from the high temperature austenitic phase field. The polygonal austenite grains are replaced by a refined structure of smaller plate shaped grains that form to accommodate the shape change associated with the transformation. It has been shown that the interface between the precipitate and the parent phase can move at velocities approaching the speed of sound.

Microstructures formed by martensitic transformations are common in alloys used as structural materials. For example, in ferrous alloys, the face centered cubic to body centered cubic (bcc) transition is often martensitic and in titanium alloys the bcc to hexagonal close packed (hcp) transition is also often martensitic. In microstructures that results from martensitic transformations, there are common orientation relationships between the phases that align the closest packed layer of the parent phase with the closest packed layer of the child phase. For example, in titanium alloys, the $\{110\}$ planes of the high temperature bcc phase are aligned with the $\{0001\}$ planes of the low temperature hcp phase.

Fig. 28 EBSD map of a fully martensitic steel formed by quenching.

Conclusion

The shapes, orientations, and arrangements of crystals within polycrystalline solids vary widely and define what we call microstructure. The single feature that has the strongest influence on the microstructure is the processing route. Inorganic solids can be formed by solidification, the sintering of powders, vapor deposition, recrystallization, or phase transformation and each path leads to a distinct microstructure. The energies of the interfaces between the crystals have an excess energy and during thermal annealing, this excess energy provides a driving force for the microstructure to evolve in a way that reduced the total interface energy.

Abstract

Orientation texture describes the distribution of crystallographic orientations of the constituent grains in polycrystalline materials. Crystallographic orientation describes the orientation of the crystal lattice with respect to a sample reference frame. Texture evolves during materials processing and is often the governing factor in the degree of anisotropy exhibited in the physical properties of crystalline materials. Texture is typically measured using X-Ray or neutron diffraction pole figures or individual orientation measurements obtained by electron backscatter diffraction. Various statistical treatments have been developed to analyze the texture data – the key element being the orientation distribution function or ODF.

Key points

- Show the link between crystallographic texture and anisotropy in materials properties.
- Provide the framework for describing crystallographic orientation both mathematically and graphically.
- Introduce the methods used for both collecting and statistically analyzing orientation data.
- Give some examples of texture analysis in polycrystalline materials.

Fig. 1 Schematic of elastic moduli measured for stresses applied along the $\langle 111 \rangle$ (body diagonal) and $\langle 100 \rangle$ (normal to the cube faces) crystal directions in a body centered cubic crystal.

Introduction

Many single crystals exhibit properties that vary with direction (anisotropy). For example, consider the elastic modulus of a copper single crystal illustrated schematically in Fig. 1. The elastic modulus measured for an applied uniaxial tensile stress parallel to the $\langle 111 \rangle$ crystal direction (i.e. the body diagonal) is nearly three times larger than the modulus measured with a stress axis parallel to $\langle 100 \rangle$ (i.e. normal to the cube faces).

Most materials are not single crystals; but polycrystals. To first order, a given property that varies with direction, such as the elastic modulus, can be approximated for a polycrystal by averaging the property for each constituent crystal. For example, if the elastic stiffness of a single crystal is represented as a fourth order tensor – C_{ijkl} then one approximation of the average elastic stiffness tensor ($\bar{C}_{ijkl}$) for the polycrystal is given as follows:

$$\bar{C}_{ijkl} = \frac{1}{V} \sum_{n=1}^N v(\mathbf{g}^n) g_{ip}^n g_{jq}^n g_{kr}^n g_{ls}^n C_{pqrs} \quad (1)$$

Where V is the total volume of the polycrystal, $\mathbf{g}^n$ is the orientation of the n th grain in the polycrystal and $v(\mathbf{g}^n)$ is the volume of the grain. N and V are the total number and volume of grain respectively. g_{ip}^n are the components of $\mathbf{g}^n$ assuming it is given in matrix form.

If a polycrystal is composed of grains where the crystal lattices are all in similar orientations (as shown schematically in the right-hand side of Fig. 2 where grains of different color have different orientation) then the properties of the polycrystal would mimic the inherent anisotropy of the constituent crystals. If the grains were all oriented randomly (as shown schematically in the left-hand side of Fig. 2 where grains of similar color have similar orientation) then the properties of the polycrystal would not reflect the anisotropy of the constituent crystals, but would instead be isotropic (i.e. the properties would not vary with direction.).

Fig. 2 Schematic of a polycrystal with a strong texture and a polycrystal with a random texture.

Real polycrystals may vary between these two extremes depending on the processing route used to form the material. The terms preferred orientation, crystallographic texture, orientation texture or simply texture are used to describe the statistical distribution of grain orientations (Dillamore and Roberts, 1965; Bunge, 1982.) In addition to texture, the terms lattice preferred orientation (LPO) or fabric are also used within the geological community (Wenk, 1985, 2003). In fact, the term grain generally describes a domain where the orientation of the crystal lattice is the same or at least very nearly the same. A grain boundary is then an interface between two crystal lattices of different orientation.

As nearly all materials forming processes produced textured materials, the characterization of texture is an important element to understanding the relationship between microstructure and properties as well as the evolution of microstructure during processing. This article reviews the definition of crystallographic orientation and graphical representations of orientations, techniques for the measurement of texture, the mathematical formalism used in processing texture data, and a few examples of texture analysis.

Crystallographic orientation

Orientation descriptions

In order to describe a crystallographic orientation, two coordinate systems must be defined: one for the sample, referred to as $\mathbf{X}^S$ and one for the crystallite, $\mathbf{X}^C$. The choice of sample axes is somewhat arbitrary, however, the choice usually follows the sample shape or processing used to form the sample. For example, consider a coupon obtained from rolled sheet and the orientation of the crystal lattice within each its constituent grains as shown in Fig. 3. It is common to assign X_1^S to the rolling direction, X_2^S to the transverse direction and X_3^S to the sample normal direction. The coordinate system for the crystallite generally follows that traditionally used in defining the unit cell, i.e. X_1^C is assigned to the $[100]$ crystal direction, X_2^C to $[010]$ and X_3^C to $[001]$. Both coordinate systems are right-handed coordinate systems. While the assignment of the reference frame to a cubic crystal, as given here, is straightforward, the assignment is less straightforward for other crystal systems such as hexagonal. Nonetheless, a coordinate system can be assigned, e.g. for a hexagonal crystal one convention is $X_1^C \parallel [2\bar{1}\bar{1}0]$, $X_2^C \parallel [01\bar{1}0]$ and $X_3^C \parallel [0001]$.

There are many ways to describe the orientation of a crystal with respect to the coordinate system of a sample. The most common is the $(hkl)[uvw]$ notation (sometimes referred to as metallurgical notation) where (hkl) are the Miller indices of the plane perpendicular to the sample normal (generally X_3^S) and $[uvw]$ describes the crystal direction parallel to X_1^S . However, as integers are used, this description is not as convenient for describing any arbitrary orientation. In texture analysis, a common way to describe the orientation of the crystal lattice with respect to a sample reference frame is to use three Euler angles. In this case, the Euler angles describe three successive rotations that bring the sample reference frame into coincidence with the crystal reference frame as shown in Fig. 4.

The various descriptions are equivalent and can be converted from one description to another as shown in Fig. 5.

Fig. 3 Schematic of the coordinate system fixed to the sample, $\mathbf{X}^S$ and the coordinate system fixed to individual crystals, $\mathbf{X}^C$.

Fig. 4 Schematic showing the definition of the three Euler angles, φ_1 , Φ , φ_2 .

Fig. 5 Two equivalent descriptions of crystallographic orientation: Euler angles and standard plane normal and crystal direction notation (i.e. $(hkl)[uvw]$).

A matrix, $\mathbf{g}$, can also be used to describe the orientation. It can be derived from the Euler angles according to:

$$\begin{bmatrix} \cos \phi_1 \cos \phi_2 - \sin \phi_1 \sin \phi_2 \cos \Phi & \sin \phi_1 \cos \phi_2 + \cos \phi_1 \sin \phi_2 \cos \Phi & \sin \phi_2 \sin \Phi \\ -\cos \phi_1 \sin \phi_2 - \sin \phi_1 \cos \phi_2 \cos \Phi & -\sin \phi_1 \sin \phi_2 + \cos \phi_1 \cos \phi_2 \cos \Phi & \cos \phi_2 \sin \Phi \\ \sin \phi_1 \sin \Phi & -\cos \phi_1 \sin \Phi & \cos \Phi \end{bmatrix} \quad (2)$$

The matrix representation is particularly useful for describing orientation in computer algorithms. Other representations that lend themselves well to implementation in the computer are Rodrigues Vectors and Quaternions (Morawiec, 2003). These are more compact representations than the matrix form but, as with matrices, they allow for easy numerical manipulation.

The rotation of the sample reference frame into coincidence with the crystal reference frame is termed a passive rotation. Conversely, rotating the crystal reference frame into coincidence with the sample reference frame is termed an active rotation.

Symmetry

The three Euler angles form a bounded space: $0 \leq \phi_1 < 2\pi$, $0 \leq \Phi < \pi$, $0 \leq \phi_2 < 2\pi$. As most crystals exhibit some degree of symmetry, for any given crystallographic orientation, there exist other symmetrically equivalent orientations. For example, consider a material with cubic crystal symmetry. There are 24 symmetry elements for a cube: the four-fold rotations about axes normal to the faces of the cube (i.e., 90° rotations about the $\langle 001 \rangle$ crystal directions) the two-fold rotations about the face diagonals (180° rotations about $\langle 110 \rangle$) and the three-fold rotations about the body diagonals (120° about $\langle 111 \rangle$). Thus, for any orientation of a cubic crystal there are 24 equivalent orientations within Euler space. A space can be defined within Euler space containing only asymmetric orientations. An example is shown for cubic symmetry in Fig. 6. This subspace is termed the asymmetric domain or the fundamental zone. However, it is important to note that the fundamental zone is not the same for each crystal symmetry (Morawiec, 2003).

Fig. 6 The asymmetric domain for cubic crystal symmetry.

Since texture is a statistical distribution of orientations, another type of symmetry must also be considered, namely sample symmetry. Sample symmetry arises from the symmetry inherent to the forming process. Consider for example the rolling of sheet metals. This forming operation has orthotropic symmetry. For a rolled cubic material, the four orientations shown in Fig. 7 would appear with the same statistical frequency in the microstructure. Thus, the term statistical symmetry is a more accurate description.

If the matrix notation is used, then the symmetry operations can be applied as follows:

$$\mathbf{g}^e = \mathbf{L}_i \mathbf{g} \mathbf{R}_j \quad (3)$$

Where $\mathbf{g}^e$ denotes an equivalent orientation, $\mathbf{L}_i$ is one of the crystal symmetry elements and $\mathbf{R}_j$ is one of the statistical symmetry elements. Because of the form of this relation, the crystal symmetry is sometimes referred to as left-handed symmetry and the statistical symmetry as right-handed.

Graphical descriptions

Pole figures provide a graphical representation of orientation. A pole figure is a two-dimensional graphical representation of orientation showing the orientation of a selected plane normal (a pole) with respect to the sample reference frame. The pole is a vector in three-dimensional space. If one imagines a hemisphere surrounding a crystal unit cell, then a pole would intersect the hemisphere at some location in three-dimensional space. The intersection location can be projected into a two-dimensional plot using a variety of projection schemes. An example of a pole figure is shown in Fig. 8, this pole figure shows the (0001) and (10 $\bar{1}$ 0) poles for a hexagonal crystal, note that there is only one pole for the (0001) plane and 3 for the (10 $\bar{1}$ 0) plane. The additional poles in the (10 $\bar{1}$ 0) case arise from crystal symmetry. In the pole figures, poles from the negative hemisphere are shown in gray. Fig. 9 shows three common “projection schemes” found in the literature (the equal angle is not a projection in the strictest sense; but, rather, a mapping of the polar angle).

A complement to the pole figure is the inverse pole figure. An inverse pole figure shows the location of a sample direction relative to the crystal reference system. For pole figures the plane of interest is selected, whereas in inverse pole figures the sample direction of interest is selected. It is bit more intuitive to think of an inverse pole figure as showing which plane normal in the crystal is parallel to the selected sample direction. Fig. 10 shows an example. In this case, it shows the poles aligned with the sample normal (X_3^S) for three different orientations as well as the poles aligned with the X_1^S sample direction. Because of crystal symmetry, the full circle need not be displayed, only the asymmetric portion of it.

While pole figures and inverse pole figures are useful representations of orientations, they provide only a partial description of orientation. For example, consider the (0001) pole figure shown in Fig. 8. While the orientation of the (0001) pole is known, the rotation of the crystal about this pole is unknown. A second pole figure (such as the (10 $\bar{1}$ 0)) is needed to completely fix the orientation. When the orientations of many crystallites are displayed, the use of multiple pole figures is quite limited. In this case, it is more productive to show the orientations in constant angle sections of Euler space. Fig. 11 shows 30,000 discrete orientations from rolled copper in a portion of Euler space along with the corresponding (111) pole figure.

Texture measurement techniques

X-ray diffraction

There are essentially two ways of measuring textures, measuring pole figures or measuring the orientations of individual grains. Until recently most textures have been measured using pole figures obtained by X-Ray or neutron diffraction. The governing equation for a pole figure is Bragg's law.

$$\lambda = 2d_{hkl} \sin \theta \quad (4)$$

where λ is the wavelength of the X-Rays, d_{hkl} is the interplanar spacing of pole figure to be measured (recall that the pole is the normal to a (hkl) plane) and θ is the Bragg angle as shown in Fig. 12.

In a pole figure measurement, a sample is placed in a goniometry so that the sample can be rotated while under the X-ray beam. For each rotation (in both Ψ and ϕ), the signal from those grains satisfying Bragg's law is measured as shown in Fig. 13. An intensity value is measured at successive tilts (Ψ) and rotations (ϕ) of the sample.

This is typically done for a series of pole figures. For example, for a base-centered cubic material, the (110), (200) and (112) pole figures are typically measured. A similar approach is employed for neutron diffraction. The major difference is that X-ray pole figures are typically measured in a reflective mode whereas neutron diffraction is done in transmission. Thus, neutron measurements have the advantage of providing a volumetric measure of texture, whereas the signal for x-rays comes from the surface of the sample. Various corrections must be applied to the pole figures to account for defocusing and absorption effects.

An alternative to pole figure measurement is the use of High-Energy X-Ray Diffraction Microscopy (HEDM) to non-destructively measure individual crystallites in the volume of sample (Pokharel, 2018). This approach has also been adapted to work in the laboratory setting using diffraction contrast crystallography (Holzner et al., 2016).

Fig. 12 Diagram showing the pole figure measurement geometry.

Fig. 13 Schematic showing grains satisfying the Bragg condition for successive 5° rotations about the sample normal (ϕ).

Electron backscatter diffraction

In the last three decades, the automation of electron backscatter diffraction (EBSD) in the scanning electron microscope (SEM) has made it practical to measure textures using the orientations of individual grains.

In EBSD, a highly tilted sample ($\sim 70^\circ$) is placed in the SEM as shown in Fig. 14. When a stationary electron beam impinges on a grain in the sample, a diffraction pattern is generated. The pattern is a function of the orientation of the lattice within the diffracting volume. As the electron beam is moved from grain to grain the diffraction pattern changes.

The pattern is imaged on a phosphor screen and transmitted to a computer using a high-gain camera. The orientation of the lattice in the diffracting volume can be derived from the pattern. This can be done automatically in the computer. The computer also controls the location of the beam on the sample. Typically, the beam is stepped across the sample to form a regular scan grid as shown in Fig. 15. An orientation measurement is made at each point in the grid. This process is fully automated and current rates exceed 5000 measurement points per second.

Despite the rapid measurement provided by automation, EBSD does not generally sample as many grains as the conventional X-Ray pole figure technique. However, EBSD has the advantage of spatially specific measurements of orientations allowing not only the distribution of orientations to be characterized, but misorientations and local texture gradients as well. If the texture is the sole focus of the EBSD analysis it is prudent to measure larger areas with a coarser step size so as to sample as many grain orientations as possible.

Fig. 14 Schematic of electron backscatter diffraction.

Fig. 15 Schematic of automated electron backscatter diffraction.

Rauch and Véron (2005) and Rauch et al. (2008) have automated orientation determination from electron diffraction spot patterns in the TEM to the state where this technique is now practical for texture measurements. Precession is used to acquire spot patterns with nearly double the number of spots as would appear in conventional selected area electron diffraction patterns. This allows rapid and reliable measurements of individual orientations on a scan grid similar to the EBSD approach but using template matching for orientation determination. However, given the limited area typically sampled in a TEM foil, the technique can be used to measure textures only in nanostructured materials.

Mathematical constructs

Basic equations

The basis of texture analysis is the orientation distribution function or ODF. The ODF is a probability density function describing the probability of finding a grain with an orientation, g , within a given angular distance, Δg , of a specified orientation, g_o , in a polycrystal; or, alternatively, the volume fraction of material oriented within Δg of g_o . These two descriptions are related through the following equation.

$$\frac{\Delta V_{(g_o+\Delta g)}}{V} = \oint_{g \in (g_o+\Delta g)} f(g) dg \quad (5)$$

Where the quantity to the left side of the equation is the volume fraction of material oriented within Δg of g_o and the function $f(g)$ inside the integral is the ODF. It should be noted that the following condition must be met for a density function:

$$\oint f(g) dg = 1 \quad (6)$$

where the integration is carried out over all of orientation space. The ODF gives the probability of finding a grain in a polycrystal with a specific orientation. If, for example, $f(g)$ is 3 then the chance of finding a grain with orientation, g , would be 3 times greater than that expected in a polycrystal with a random distribution of orientations. An ODF

$$f(g) = \sum_{l=0}^{\infty} \sum_{m=-l}^l \sum_{n=-l}^l C_l^{mn} T_l^{mn}(g) \quad (7)$$

may be represented as a sum of generalized spherical harmonics $T_l^{mn}(g)$ weighted by the so called C-coefficients C_l^{mn} . This representation is especially useful for the computation of mean tensorial properties as discussed in a subsequent section as for the computation of pole figures. While the direct computation of the sum in Eq. (7) is numerically challenging and is generally performed up to a maximum rank of $l = 34$, recent algorithms, which make use of fast Fourier techniques allow for the evaluation of the series expansion up to degree 200 reducing truncation errors (Potts et al., 2009; Hielscher, 2015). Kalidindi et al. (2009) have demonstrated that the fast Fourier techniques can be used in alternate series expansion schemes to estimate the ODF.

A pole figure can be derived through integration of the ODF along a specific path in orientation space according to

$$P_h(\mathbf{y}) = \frac{1}{2\pi} \int_{h||\mathbf{y}} f(g) d\chi \quad (8)$$

Where $P_h(\mathbf{y})$ is the pole figure, $\mathbf{h}$ represents the (hkl) of the pole figure (a vector in the crystal reference frame), $\mathbf{y}$ is a vector in the pole figure (i.e. a vector in the sample reference frame represented by the rotation and tilt angles, ϕ and Ψ introduced previously). The integration is carried out along the path, χ , where $\mathbf{h}$ and $\mathbf{y}$ are coincident. With the C-coefficients C_l^{mn} from Eq. (7) the pole figures may be represented as sum of spherical harmonics, $k_l^n(\mathbf{y})$:

$$P_{h_i}(\mathbf{y}) = \sum_{l=0}^{\infty} \frac{4\pi}{2l+1} \sum_{m=-l}^l \sum_{n=-l}^l C_l^{mn} k_l^{*m}(\mathbf{h}_i) k_l^n(\mathbf{y}) \quad (9)$$

ODF estimation from individual orientations

The objective of texture analysis is to process the pole figures or the individual orientation measurements to determine the ODF. It is easiest to conceptualize the ODF determination using the individual orientation measurements. Consider a set of orientation measurements, where the orientations can be described as points on a number line as shown schematically in Fig. 16. If the line is partitioned into a finite set of bins, then the number of orientations in each box can be counted and a histogram constructed as shown. A curve can then be fit to the histogram. The resulting curve is essentially the ODF.

It should be noted that the distribution of orientations shown schematically in Fig. 16 could be described using other distributions as shown in Fig. 17 depending on the size of the bins used to form the histogram. The choice is somewhat arbitrary; however, tensor properties, like elastic anisotropy or piezoelectricity, rely only on a low order description of texture and, hence, are not so sensitive to choice of bin size.

Fig. 16 A schematic of the determination of the ODF from individual orientation measurements.

Fig. 17 Schematic showing lower and higher order descriptions of the texture shown in Fig. 16.

A second approach to determining the ODF from individual orientations is to estimate its C -coefficients according to the formula:

$$C_l^{mn} = \frac{2l+1}{N} \sum_{i=1}^N K T_l^{mn}(g_i) \quad (10)$$

where g_i represents one orientation from a set containing N individual orientation measurements. K is a smoothing factor. If single orientation measurements are made where only one measurement per grain is recorded then a weighting factor proportional to the grain area must also be introduced.

When estimating the ODF from individual measurements it is important that enough measurements are collected to ensure statistical reliability no matter the approach used to calculate the ODF (Hielscher, 2013; Wright et al., 2007). While scans with a fine step size are helpful for reconstructing the microstructure they may not be well suited for characterizing the texture of a sample. Fig. 18 shows an example from the cross-section of an aluminum bar. Two EBSD scans were measured, both containing approximately 1 million individual orientation measurements but collected at different magnifications in the microscope. The scan in Fig. 18A is excellent for reconstructing the microstructure but only samples a handful of grains whereas Fig. 18B does not give as good of a reconstruction of the microstructure it provides a very good measurement of the texture with over 29,000 grain orientations sampled. In both cases the orientation maps are constructed to show the crystal direction aligned with sample normal according to the stereographic triangle color legend – this color mapping scheme is used for all subsequent orientation maps. Note the lack of symmetry in the horizontal direction in the pole figures in Fig. 18 corresponds to the texture gradient visible in the corresponding orientation map of the sample. The left edge of the scan is near the surface of the bar.

Fig. 18 Orientation map (showing the crystal direction aligned with the normal direction of the sample) reconstructed from two EBSD datasets on the cross-section of an aluminum bar along with pole figures calculated from the EBSD data using the harmonic method. (A) 1.02 million point dataset at a high magnification (B) 1.06 million point dataset collected at a low magnification.

ODF estimation from diffraction pole figure measurements

Unlike textures measured using individual orientations, it is important to note that there is no one-to-one relationship between measured pole figure data and ODFs. The ambiguity has two major reasons. First the limited number of pole figures available from X-ray measurements. This is illustrated in Figs. 19 and 20 which display 8 pole figures for two entirely different ODFs, 6 of which are completely identical.

The second source of ambiguity is the fact that in the integral equation (7) the odd order C-coefficients are mapped to zero and, hence, cannot be reconstructed from diffraction pole figures without additional assumptions. The effect of this ambiguity is illustrated in Fig. 21 which displays two radially symmetric ODFs with all pole figures being identical. Usually, the ODF with its peak at the component is considered to be the true ODF and the peaks at distance of 180° from the preferred orientation in the second ODF are referred to as ghosts (Matthies, 1980).

While there are multiple methods of performing the data reduction from the pole figures, three have emerged as the most common: the Harmonic, the WIMV and the MTEX methods. The WIMV (an acronym formed from the names of the originators of the technique) is essentially a binning method as outlined previously whereas the Harmonic method uses a series expansion approach, converting the orientation measurements directly to an ODF.

Harmonic method

The historically first method for reconstructing ODFs from diffraction pole figures was the series expansion using a set of harmonic functions developed independently by Bunge (1965) and Roe (1965). The harmonic method utilizes Eq. (9) to compute the C-coefficients C_l^{mn} of the ODF from the pole figure intensities by solving a set of systems of linear equations. These systems are well posed up to a maximum series expansion, l , which depends on the crystal symmetry and the number of pole figures measured. Since

Fig. 19 Pole figures of an ODF from a material with orthorhombic crystal symmetry with preferred orientations at $(0,90,0)$, $(90,0,0)$ and $(90,90,270)$ Euler angles.

Fig. 20 Pole figures of an ODF from a material with orthorhombic crystal symmetry with preferred orientations at $(0,0,0)$, $(90,90,0)$ and $(180,90,90)$ Euler angles.

Fig. 21 Two triclinic radially symmetric ODFs which have the same even order C -coefficients and, hence, exactly the same pole figures. The small peak at 180° of the blue ODF is usually referred to as ghost effect.

the maximum harmonic degree, l , is generally quite low, sharp ODFs reconstructed by the harmonic method typically suffer from truncation errors. As mentioned previously this is not a major concern when dealing with physical properties as those depend only on the lower order C -coefficients, e.g., for characterizing elastic anisotropy arising from texture, the harmonic series need only be expanded out to $l = 4$. Another drawback of this approach stems from the fact that in diffraction pole figures all odd order C -coefficients C_l^m are zero and, hence, the odd order C -coefficients of the reconstructed ODF are zero as well. This might result in negative values in the reconstructed ODF which are not allowed for density functions and makes ghost correction impossible.

WIMV method

The WIMV-method was initially described in [Matthies and Vinel \(1982\)](#) and later refined by [Lutterotti et al. \(1997\)](#). In contrast to the harmonic method it is based on a discretization of the orientation space into boxes resulting in a piecewise constant ODF. The relation between the ODF values at these boxes and the pole figure intensities can be expressed as a large system of linear equations which is solved iteratively. The iterative solver is designed to allow only positive values for the ODF, which is a big advantage over the harmonic method. One of the challenges of this technique is the ambiguity of Euler space at $\Phi = 0^\circ$. At $\Phi = 0$, ϕ_1 and ϕ_2 are not fully defined but rather governed by $\phi_1 + \phi_2$ equals a constant. The volume of the bins vary as a function of Φ , bins centered on

$\Phi = 2.5^\circ$ have a volume of 0.044 rad cubed and bins centered on $\Phi = 87.5^\circ$ have a volume of 0.999 assuming $5^\circ \times 5^\circ \times 5^\circ$ bins. In contrast to WIMV, the refinements embodied in eWIMV (Lutterotti et al., 1999) applies some subsequent smoothing to the reconstructed ODF to hide the initial piecewise constant nature.

MTEX method

The MTEX method was first described by Hielscher and Schaeben (2008) and can be seen as a synthesis of the harmonic and the WIMV methods. The MTEX method relies on a discretization of the ODF by bell shaped functions

$$f(g) = \sum_{k=1}^K c_k \phi(g_k g) \quad (11)$$

which is similar to the WIMV method as it is based on a discrete grid g_k in the orientation space. Though, the g_k do not need to form a regular grid but are usually placed to represent equal volume in the orientation space. On the other hand, the discretization (11) directly translates into a representation of the ODF in terms of generalized spherical harmonics:

$$f(g) = \sum_{l=0}^{\infty} \hat{\phi}(l) \sum_{m=-l}^l \sum_{n=-l}^l T_l^{mn}(g) \sum_{k=1}^K c_k T_l^{mn}(g_k) \quad (12)$$

The MTEX method uses representation (11) to ensure the non-negativity of the ODF and representation (12) to link the ODF with the pole figures by equation (9). The transition between representation (11) and (12) is done via a fast Fourier transform in orientation space. The coefficients c_k are computed from the pole figure intensities by iteratively solving a system of linear equations.

Examples

Thin films

Thin films are typically characterized by the alignment of a particular crystallographic axis with the sample normal. Fig. 22A shows a (111) pole figure for an aluminum thin film. The axisymmetric character of this material is sometimes called a (111) fiber texture. Some thin film properties (such as the mean time to failure in microelectronic devices) have been correlated to the sharpness of the fiber texture. An axisymmetric texture can be more simply analyzed by a pole plot as shown in Fig. 22B. The pole plot is essentially a slice through the pole figure as shown. For more accurate results, the pole plot can be improved by averaging azimuthally.

While the pole plot is helpful for analyzing thin film textures, calculating the pole figures to verify that the texture is truly axisymmetric is always recommended. For example, in a copper thin film, a (111) fiber texture is expected. However, other fibers may also be present. The axisymmetric nature of the texture can be confirmed using a pole figure and the presence of other fibers discovered using an inverse pole figure as shown in Fig. 23.

Rolled sheet

One of the most studied materials using texture analysis is rolled aluminum sheet for beverage cans. The texture of this material must be as well controlled as possible in order to produce stock well suited for the deep drawing of cans. A typical (111) pole figure for rolled aluminum is shown in Fig. 24.

The bulk of the orientations typically lie within a “fiber” in Euler space as shown in Fig. 25. In order to simplify the analysis of rolled face-centered cubic (fcc) materials such as aluminum, components associated with key locations along this fiber have been identified. These key components are shown in Euler space and in a (111) pole figure.

Fig. 22 (A) (111) Pole figure and (B) corresponding pole plot from an aluminum thin film.

Fig. 23 (A) (111) Pole figure and (B) an inverse pole figure for a copper thin film.

Fig. 24 (111) Pole figure calculated using the harmonic method on individual orientation measurements obtained using EBSD on rolled aluminum. Orthotropic sample symmetry was enforced in the calculations.

Fig. 25 (A) Table ideal components for face-centered cubic rolling textures. (B) location of ideal texture components in (A) shown in a (111) pole figure. (C) texture fibers shown in Euler angle space.

An FCC rolling texture can then be simply characterized by the intensities of these ideal components. This approach has been successfully used in refining the thermomechanical processes of rolled aluminum to achieve textures that optimize the deep-drawing performance of beverage can stock. Different fibers or texture components are used in rolled steel (Kocks et al., 1998) or in rolled hexagonal materials (Tenckhoff, 1988).

Fig. 26 shows the evolution of texture in a cold-rolled interstitial free steel. Note that the initial texture is relatively random but increases in both intensity but also in reflecting the orthotropic symmetry of the rolling process with increasing reduction.

Fig. 26 Pole figures for successive cold-rolling reductions of an interstitial-free steel as measured by EBSD and analyzed using the harmonic method. The intensities are given in multiples for a random distribution.

Other texture related entities

Misorientation

To this point, the orientation of a crystal has been described relative to the sample coordinate system. However, the orientation of one crystal could also be described relative to the coordinate system associated with a neighboring crystal. Such a description is more often denoted a misorientation (or alternatively a disorientation or orientation difference). While misorientations can be described similar to orientations, i.e. in terms of Euler angles or matrices, it is usually more convenient to describe them in terms of an axis-angle pair. For two crystals in any two orientations, it is always possible to find a common axis around which one crystal can be rotated until it is in coincidence with the other. The misorientation can thus be described as a rotation about the common axis. As with orientation, crystal symmetry plays a role in the description of misorientations. For example, for a crystal with cubic symmetry there are 24 symmetrically equivalent orientations. Thus, for a misorientation between two cubic crystals, there are 576 (24×24) symmetrically equivalent misorientations. This is realized in axis-angle space as essentially 24 axes of rotation, each of with a specific angle of rotation associated with it and 24 different permutations of the indices describing the axes. Generally, the misorientation from the symmetrically equivalent set of misorientations of minimum angle of rotation is used to and is called the disorientation. In the same manner as ODFs, Misorientation Distribution Functions (MDFs) may also be calculated. However, point specific measurements are needed so EBSD is generally used to acquire the misorientation data for MDF calculations.

Fig. 27 shows an example for a bend-specimen of titanium (primarily the hexagonal close packed α phase). The material accommodates strain through twinning. Four types of twins are expected, two tensile types and two compressive types. There is a good mix of the tensile twin described by a 94.8° rotation about the $\langle \bar{1}2\bar{1}0 \rangle$ crystal direction as well as the compression twin of 64.3° rotation about $\langle \bar{1}100 \rangle$ accompanied by a few 34.8° rotation about $\langle \bar{1}100 \rangle$ twins. However, the 57.0° rotation about $\langle \bar{1}2\bar{1}0 \rangle$ compression twins were not observed. The balance between these different twins can be quantified using the MDF. The MDF shown in Fig. 27B is shown for axis-angle space, where the constant sections are for successive disorientation angles and the sections are given in the stereographic unit triangle for hexagonal crystal symmetry. While, in this case, the twins were known, in a material where the twins were unknown, the MDF could be utilized to identify the most important boundary types. This methodology can also be used, for example, to find specific boundaries susceptible and/or resistant to damage, or boundaries prone to grain boundary sliding.

The terms grain boundary texture and mesotexture are sometimes used to describe the texture associated with misorientation at grain boundaries. When 3D data is acquired via EBSD and serial sectioning or HEDM then the link between misorientation and the orientation of the boundary plane can be characterized through five dimensional distribution function analysis (Rohrer and Randle, 2009).

Fig. 27 (A) EBSD pattern quality map for an α titanium bend sample overlaid with tensile and compression twins. (B) Misorientation distribution function for boundaries greater than 15° with the tensile and compression twins highlighted. The non-faded portions correspond to the asymmetric domain for hexagonal symmetry in axis-angle space that show the asymmetric domain.

Microtexture

As a material deforms, the orientations of individual grains rotate due to slip of specific crystallographic planes in the material. Orientation gradients will form within grains and may also fragment into subgrains. The local variation in orientation within individual grains is often termed microtexture. In general, the ODF based analysis is not employed in analyzing microtextures but rather the study of local disorientations is used (Wright et al., 2011). Fig. 28 shows an example from an in-situ tensile test of a medium carbon steel sample. EBSD measurements on the surface were performed as the sample was held in tension at increasing levels of strain. For each EBSD scan, the spread in the orientation within the individual grains was tracked. As the strain increases, the spread in orientation also increases (Wright et al., 2016). The variation in orientation is also visible in the orientation map as evidenced by the subtle changes in color within the individual grains.

Materials properties and modelling

Tensor averaging

One way to capture the anisotropic materials properties is through the use of tensors as shown in Nye's classic text on the subject (1957). When individual orientation measurements collected on a regular grid are used to characterize the texture of a polycrystal

Fig. 28 Orientation maps reconstructed from in-situ EBSD measurement on a tensile steel sample prior to the tensile test and at 10% strain. Corresponding plot of orientation spread as a function of strain.

(as is the case for EBSD measurements) then if the property tensor for the single crystal is known the upper or Voigt bound for the polycrystal property tensor can be determined as shown for a fourth rank tensor in Eq. (1). In this case, each orientation is simply weighted by 1. The lower or Reuss bound can be determined similarly but employing the inverse of the property tensor. For example, for elastic anisotropy the stiffnesses (C_{ijkl}) are used to calculate the Voigt bound and the compliances (S_{ijkl}) are used to calculate the Reuss bound as shown in Eq. (13).

$$\bar{S}_{ijkl} = \frac{1}{N} \sum_{n=1}^N g_{ip}^n g_{jq}^n g_{kr}^n g_{ls}^n S_{pqrs} \quad (13)$$

Fig. 29 shows an example for a 95% cold-rolled interstitial free steel. In this figure, Young's modulus at several points in the microstructure (a region from the data used to construct the textures shown in Fig. 27) is shown and as well as the bulk average as calculated from the texture. The average Young's modulus is the average of the Voigt and Reuss bounds for the sample (Fig. 29).

Bunge (1982) has also shown that if the C_l^{mn} -coefficients of the harmonic series expansion are determined, then these can also be used to estimate a given property tensor for a bulk materials in conjunction with the single crystal property tensor. It should be noted that the rank of the C_l^{mn} -coefficients used in the estimation would be on the same order as the rank of the tensor. For example, for elastic stiffnesses the rank of the tensor is four and thus, only C_l^{mn} -coefficients up to a rank of $l = 4$ are used in the calculation. While we have used the example of elastic stiffness here, the same principles can be applied to other properties which lend themselves to the tensorial representation. Average property tensors of any order can be computed as demonstrated by Mainprice et al. (2011) using fast algorithms. For example, Mainprice et al. (2014) have computed the average anisotropic piezoelectric property tensor from texture data which is a third rank tensor.

Several authors have proposed methodologies to derive a representative set of weighted individual orientations from an ODF (Eisenlohr and Roters, 2008; Toth and Van Houtte, 1992; Kocks et al., 1990; Melchior and Delannay, 2006). Such methods can be applied to an ODF calculated using any approach. The representative set of orientations and their weights can then be used in the manner shown in Eq. (1) to calculate a bulk polycrystal property tensor.

Modelling

This section is not intended to provide comprehensive coverage of the wealth of models that have been developed to simulate the evolution of texture during deformation; but, rather provide a brief introduction to this field of research.

Two basic approaches are the Sachs (1929) and Taylor (1938) models. In the Sachs model each grain in the polycrystal is assumed to experience the same amount of stress whereas in the Taylor model each grain is assumed to undergo the same amount of strain. Furthermore, in the Sachs model the strain is achieved through slip on a single slip system; whereas for the Taylor model deformation is accommodated through slip on multiple slip systems. In the Sachs model equilibrium is satisfied at the grain boundaries but the compatibility conditions are not which leads to gaps and overlaps between the grains. The converse is true in the Taylor model – the compatibility conditions are met between the grains but the equilibrium at grain boundaries is not. The Taylor model is well suited for large strains where it is unlikely any single grain will deviate much from the average.

In terms of texture evolution, it is important to recall that slip produces grain rotation. Thus, effective modelling of the slip enables the evolution of texture to be predicted. Adaptations of these models and other more sophisticated models have been developed since these early models such as the relaxed constraints Taylor model, the self-consistent model (Kröner, 1961; Budiansky and Wu, 1962; Molinari et al., 1987) and the viscoplastic model (Asaro and Needleman, 1985). One adaptation is to

Fig. 29 Map reconstructed from a subset of the EBSD data obtained on the 95% cold-rolled steel sample shown in Fig. 26. The color in the map shows the crystal direction aligned with the normal direction, the gray scale reflects the relative quality of the EBSD pattern at each point in the scan. Schematics of Young's modulus at selected locations in the microstructure are shown along with the Voigt-Reuss average for the full dataset.

essentially embed a polycrystal plasticity model into each individual element of a Finite-Element Model (Beaudoin et al., 1994; Van Houtte et al., 2005; Roters et al., 2010). This then allows some of the limitations of these models to be overcome and applied to the simulation of polycrystals in complex geometries with heterogeneous boundary conditions and in three dimensions. Other adaptations include the treatment of materials which deform not only by slip but also by mechanical twinning (Beyerlein and Tomé, 2010) and also more complexity in the treatment of strain hardening on the slip systems (Rollett and Kocks, 1993).

Another area of modelling is that of recrystallization and grain growth. A good overview of the subject is given by Rollett (1997). Important areas of research include the balance between oriented nucleation versus oriented growth and the role grain boundaries play in these processes, both in terms of the orientation of the boundary planes as well as the misorientations between neighboring grains (Rollett, 2013).

Conclusion

Texture analysis focuses on the distribution of lattice orientations of the constituent grains in polycrystalline materials. Texture is typically measured using X-Ray or neutron diffraction pole figures or individual orientation measurements obtained by electron backscatter diffraction or high energy X-Ray diffraction. Various mathematical methods have been developed to reduce the texture data to the core orientation distribution function in three-dimensional orientation space. Analysis of the ODF through various data can provide understanding on the governing mechanisms in the evolution of the microstructure during thermo-mechanical processing. It can also be used to predict anisotropy in the physical properties of crystalline materials.

Ψ	wave function

Introduction

At the atomic scale, electronic states are typically characterized by discrete energy levels that are often separated by electron volts; the spatial distribution of these states is highly localized. In contrast, electronic states in crystalline matter are typically characterized by energy bands: the energy states form a quasicontinuous spectrum with delocalized spatial distributions. At the nanoscale, the distribution of energy states resides between these limits. This evolution of energy levels from an atom to large clusters to “quantum dots” is illustrated in Figure 1. A large cluster in this scheme may possess hundreds or thousands of atoms. When its surface is

Figure 1 Schematic energy levels for an atom, a cluster, and a quantum dot.

electronically passivated, such large clusters are called quantum dots. While the energy spacing between electronic levels in a quantum dot is not quasicontinuous, it is usually too small to be measured. For example, the spacing may be much smaller than the thermal energy associated with a vibrational mode.

Understanding the evolution of the electronic structure of matter at the nanoscale is a challenging task. Matter at this length scale is not especially amenable to techniques based on atomic or macroscopic descriptions, as the spatial and energetic distribution of electron states are quite disparate. Methods for calculating the electronic properties of these systems usually start from either the atomic or molecular limit or from the solid-state limit. Atomic or molecular methods are often not equipped to handle the large number of atoms or electrons in nanoscale materials whereas solid-state methods often require translational symmetry, which is not present for confined systems. Moreover, the electronic interactions and spatial extent of wave functions at the nanoscale can be remarkably different than either the atomic or macroscopic limit.

An electron confined within a one-dimensional box of size a is considered. The lowest energy level of this system is given in elementary textbooks as

$$E = \frac{\pi^2 \hbar^2}{2ma^2} \quad [1]$$

where $\hbar$ is the Planck constant divided by 2π , and m is the mass of the particle, for example, the mass of an electron. If the size of the box is reduced, then E increases.

This phenomenon, that is, the energy level spacing increasing with reduced dimensionality, is called quantum confinement. Quantum confinement can be readily understood from the Heisenberg uncertainty principle. The uncertainty principle states that the uncertainty in momentum and position must be such that the product exceeds $\hbar/2$:

$$\Delta p \cdot \Delta x \geq \frac{\hbar}{2} \quad [2]$$

where Δp is the uncertainty in the momentum and Δx is the uncertainty in the position of the electron. Consider the energy of a free electron with momentum p :

$$E = \frac{p^2}{2m} \quad [3]$$

Since the uncertainty in the momentum cannot exceed the momentum itself, one can write $p > \Delta p$. As such, one has the following inequality:

$$E > \frac{\hbar^2}{8ma^2} \quad [4]$$

If one tries to localize the position of an electron by reducing the box size, its energy must increase and diverge as the confining region vanishes.

Although this very simple picture of quantum confinement is given for one dimension, it is also true for an electron confined in three dimensions. For example, if a particle is confined within a sphere whose radius is R , one might expect an energy level to vary with the radius according to

$$E(R) = E_\infty + \frac{\alpha}{R^2} \quad [5]$$

where α is a constant and E_∞ is the energy as $R \rightarrow \infty$. Suppose one considers an optical gap, E_{gap} , as the difference between the high filled and lowest empty states for a system confined in a sphere of size R . In the simplest description of the gap, one might expect E_{gap} to scale as

$$E_{\text{gap}}(R) = E_{\text{gap}} + \frac{\beta}{R^2} \quad [6]$$

where β is a constant.

Quantum confinement has been observed experimentally for nanostructures such as quantum dots of Si and CdSe. In Figure 2, a quantum dot of hydrogenated silicon is illustrated. The interior of the dot consists of silicon atoms in the bulk diamond structure; the surface of the dot is hydrogenated. Hydrogen removes any dangling bonds on the surface. As such, all the atoms in the system should be fully coordinated and should not contribute to the electronic properties of the quantum dot. Typically, a quantum dot is a

Figure 2 Ball and stick model for a quantum dot of hydrogenated silicon (left). The gray balls represent the silicon atoms, the white balls represent the hydrogens. Also shown is the corresponding optical absorption. Note the increase in gap size from the known bulk gap of silicon, which is 1.1 eV.

few nanometers to tens of nanometers in size. The smallest dots contain hundreds of atoms whereas large dots may contain hundreds of thousands of atoms.

Also illustrated in Figure 2 is the corresponding optical gap as a function of the dot size. The quantum dot gap with this size range is approximately twice the gap of crystalline silicon; silicon exhibits weak optical absorption near 1.1 eV. The absorption is weak owing to the nature of the gap in silicon. It is an indirect gap because the optical excitation couples an electron with a hole of different crystalline momentum or wave vector. Conservation of crystal momentum would require the electron and hole to have the same momentum. As such, this process can only occur by the participation of the quantized vibrational modes of the lattice or phonons, which provide the required momentum to satisfy the conservation rules. Unlike a two-body process (electron and hole), a three-body process (electron, hole, and phonon) results in a very weak interaction between light and matter.

In finite systems, crystal momentum is not well defined, owing to the lack of translation symmetry. As the system approaches nanoscale sizes, the nature of an indirect gap or direct gap becomes moot. Consequently, the optical absorption becomes stronger in quantum dots and the size of the gap increases owing to quantum confinement. An approximate fit of eqn [6] is consistent with the experimental data shown in Figure 2. This example shows the striking effect of size on the electronic structure of nanostructures, that is, silicon at this length scale is transformed from an optical inactive material to an optically active one.

Theory for the Electronic Structure at the Nanoscale

Quantum mechanical laws that describe the behavior of matter at the nanoscale were discovered in the first part of the twentieth century. Using these laws, it is possible to predict the electronic structure of matter from the atomic- to nano- to the macroscale, at least in principle. While it is relatively easy to write down the equations for interacting atoms, that is, interacting nuclei and electrons, obtaining a solution to the problem that is sufficiently accurate to make predictions is a formidable task.

Consider N nuclei of charge Z_n at positions $\{R_n\}$ for $n=1, \dots, N$ and M electrons at positions $\{r_i\}$ for $i=1, \dots, M$. This is shown schematically in Figure 3. The quantum mechanical equation for this system in its simplest form can be written as

Figure 3 Simplified picture of electrons and nuclei in matter.

$$\mathcal{H}(R_1, R_2, R_3, \dots; r_1, r_2, r_3, \dots) = \sum_{n=1}^N \frac{-\hbar^2 \nabla_n^2}{2\mathcal{M}_n} + \frac{1}{2} \sum_{n,m=1, n \neq m}^N \frac{Z_n Z_m e^2}{|R_n - R_m|} - \sum_{i=1}^M \frac{-\hbar^2 \nabla_i^2}{2m} - \sum_{n=1}^N \sum_{i=1}^M \frac{Z_n e^2}{|R_n - r_i|} + \frac{1}{2} \sum_{i,j=1, i \neq j}^M \frac{e^2}{|r_i - r_j|} \quad [7]$$

$\mathcal{M}_n$ is the mass of the nucleus. This expression omits some terms such as those involving relativistic interactions, but captures the essential features for nanoscale matter.

Using the Hamiltonian in eqn [7], the quantum mechanical equation known as the Schrödinger equation for the electronic structure of the system can be written as:

$$\mathcal{H}(R_1, R_2, R_3, \dots; r_1, r_2, r_3, \dots) \times \Psi(R_1, R_2, R_3, \dots; r_1, r_2, r_3, \dots) = E \Psi(R_1, R_2, R_3, \dots; r_1, r_2, r_3, \dots) \quad [8]$$

where E is the total electronic energy of the system and Ψ is the many-body wave function.

Soon after the discovery of the Schrödinger equation, it was recognized that this equation provided the means of solving for the electronic and nuclear degrees of freedom. Using the variational principle which states that an approximate wave function will always have a less favorable energy than the true ground-state energy, one had an equation and a method to test the solution. One can estimate the energy from

$$E = \frac{\int \Psi^* \mathcal{H} \Psi d^3 R_1 d^3 R_2 d^3 R_3 \dots d^3 r_1 d^3 r_2 d^3 r_3 \dots}{\int \Psi^* \Psi d^3 R_1 d^3 R_2 d^3 R_3 \dots d^3 r_1 d^3 r_2 d^3 r_3 \dots} \quad [9]$$

However, a solution of eqn [8] for anything more complex than a few particles becomes problematic even with the most powerful computers. Obtaining an approximate solution for systems with many atoms is difficult, but considerable progress has been made since the advent of reliable computers.

Approximations to the Electronic Structure Problem

A number of highly successful approximations have been made to solve for both the ground-state and excited-state energies of matter. These approximations are constructed to remove as many unimportant degrees of freedom from the system as possible.

For example, one common approximation is to separate the nuclear and electronic degrees of freedom. Since the nuclei are considerably more massive than the electrons, the electrons will respond instantaneously to any changes in the nuclear coordinates. This approximation is called the Born–Oppenheimer or adiabatic approximation. It allows one to treat the nuclear coordinates as classical parameters. For most condensed matter systems, this assumption is highly accurate.

Another highly useful approximation is the pseudopotential approximation. The pseudopotential model of a solid has led the way in providing a workable model for computing the electronic properties of materials. Using pseudopotentials, it is possible to predict accurately the properties of complex nanosystems such as quantum dots with hundreds, if not thousands of atoms. The pseudopotential model treats matter as a “sea of valence electrons” moving in a background of ion cores (Figure 4). The ion cores are composed of nuclei and inert inner electrons. Within this model, many of the complexities of an all-electron calculation are avoided. Since only the valence electrons are considered, a group IV solid such as C with six electrons is no more difficult than Pb with 82 electrons as both elements have four valence electrons.

Pseudopotential calculations center on replicating the wave function in the spatial region from the core, that is, within the chemically active bonding region. The smoothly varying pseudo-wave-function is taken to be identical to the all-electron wave function in the bonding regions.

A third approximation is based on the density-functional theory. Methods for understanding the electronic structure of matter based on a knowledge of the charge density have existed since the late 1920s. For example, the Thomas–Fermi description of atoms was based on a knowledge of the electronic density. This theory was one of the first attempts at a quantitative theory for the electronic structure of atoms.

Most contemporary treatments of the density-functional theory begin by considering a free electron gas of uniform charge density. The justification for this starting point comes from the observation that simple metals, such as aluminum and sodium have properties that appear to resemble those of a free electron gas. In the mid 1960s, Hohenberg, Kohn, and Sham published a classic set of papers on the density-functional theory. Their work justified the replacement of the many-body wave function by one-electron orbitals based on the electronic charge density.

A key aspect of their work is the local density approximation. Within this approximation, one can express the exchange energy as

$$E_x[\rho(r)] = \int \rho(r) \mathcal{E}_x[\rho(r)] d^3 r \quad [10]$$

where $\mathcal{E}_x[\rho]$ is the exchange energy per particle of uniform gas at a density of ρ . Within this framework, the true exchange potential is replaced by a potential determined from the functional derivative of $E_x[\rho]$:

Figure 4 Schematic of the pseudopotential model of condensed matter.

$$V_x[\rho] = \frac{\delta E_x[\rho]}{\delta \rho} \quad [11]$$

One serious issue is the determination of the exchange energy per particle, $\mathcal{E}_x$, or the corresponding exchange potential, V_x . The exact expression for either of these quantities is unknown, save for special cases. If one assumes the exchange energy to be given by the Hartree–Fock expression for the exchange energy of the free electron gas, then one can write

$$E_x[\rho] = -\frac{3e^2}{4\pi} (3\pi^2)^{1/3} \int [\rho(\mathbf{r})]^{4/3} d^3r \quad [12]$$

and taking the functional derivative, one obtains

$$V_x[\rho] = -\frac{e^2}{\pi} (3\pi^2 \rho(\mathbf{r}))^{1/3} \quad [13]$$

In contemporary theories, numerical studies have been performed on uniform electron gases resulting in local density expressions of the form: $V_{xc}[\rho(\mathbf{r})] = V_x[\rho(\mathbf{r})] + V_c[\rho(\mathbf{r})]$, where V_c represents contributions to the total energy beyond the Hartree–Fock limit. It is also possible to describe the role of spin explicitly by considering the charge density for up and down spins: $\rho = \rho_{\uparrow} + \rho_{\downarrow}$. This approximation is called the local spin density approximation.

The Kohn–Sham Equation

The work of Kohn and Sham resulted in a workable framework for the electronic structure problem. Specifically, the Kohn–Sham equation for the electronic structure of matter is given by

$$\left(\frac{-\hbar^2 \nabla^2}{2m} + V_p^{\text{ion}}(\mathbf{r}) + V_H(\mathbf{r}) + V_{xc}[\rho(\mathbf{r})] \right) \times \varphi_i(\mathbf{r}) = E_i \varphi_i(\mathbf{r}) \quad [14]$$

V_p^{ion} is the ion core pseudopotential, V_H is the Hartree or Coulomb potential, and V_{xc} is the exchange–correlation potential. The Hartree potential is obtained from

$$\nabla^2 V_H(\mathbf{r}) = -4\pi e \rho(\mathbf{r}) \quad [15]$$

where the charge density is given by

$$\rho(\mathbf{r}) = -e \sum_{i, \text{occup}} |\varphi_i(\mathbf{r})|^2 \quad [16]$$

The summation is over occupied states. When pseudopotentials are employed, these states correspond to the valence states of the system.

The Kohn–Sham equation is solved self-consistently. An approximate charge is assumed to estimate the exchange–correlation potential and to determine the Hartree potential from eqn [15]. These estimated potentials are inserted in the Kohn–Sham equation. Once the Kohn–Sham equation is solved, a new output charge density is determined from eqn [16]. The output charge density is used to estimate new exchange–correlation and Hartree potentials. The process is repeated until the input and output charge densities or potentials are identical to within some prescribed tolerance.

Given a solution of the Kohn–Sham equation, the total energy, E_T , can be computed from

$$E_T = \sum_i^M E_i - 1/2 \int \rho(\mathbf{r}) V_H(\mathbf{r}) d^3r + \int \rho(\mathbf{r}) (E_{xc}[\rho(\mathbf{r})] - V_{xc}[\rho(\mathbf{r})]) d^3r \quad [17]$$

where E_{xc} is a generalization of eqn [10], that is, the correlation energy density is included. The electronic energy as determined from E_T must be added to the ion–ion interactions to obtain the structural energies. This is a straightforward calculation for confined systems.

Owing to its ease of implementation and overall accuracy, the local density approximation is a popular choice for describing the electronic structure of matter. It is relatively easy to implement and surprisingly accurate. Recent developments have included the so-called generalized gradient corrections to the local density approximation. The generalized gradient approximation often yields accurate cohesive energies.

Computational Approaches for Nanostructures

Several methods exist for determining the electronic structure of nanostructures. These methods are often based on choosing a basis set for the electronic wave functions and directly solving the Kohn–Sham equation. For example, the wave functions can be expanded as

$$\Psi_n(\mathbf{r}) = \sum_{jk} a_{j,k}(n) \Phi_j(\mathbf{r} - \mathbf{R}_k) \quad [18]$$

where the sum is over (j, k) . These indices label the atomic positions, given by $\mathbf{R}_k$, and a local orbital, Φ_j , associated with an $(s, p, d, \dots)$ state. The local orbitals, Φ_j , can be taken to be atomic orbitals, Gaussians, exponentials, and so on. With the form of eqn [18] as the basis, the eigenvalue problem takes the form of the matrix equation:

$$\mathbb{H}^{\text{KS}} \Psi_n = E_n \mathbb{S} \Psi_n \quad [19]$$

where the Hamiltonian matrix elements, H_{lm}^{KS} , are given by

$$H_{lm}^{\text{KS}} = \sum_{jk, j'k'} a_{j,k}^*(l) a_{j',k'}(m) \int \Phi_j^*(\mathbf{r} - \mathbf{R}_k) \times H^{\text{KS}} \Phi_{j'}(\mathbf{r} - \mathbf{R}_{k'}) d^3r \quad [20]$$

and the overlap matrix elements, S_{lm} , is given by

$$S_{lm} = \sum_{jk, j'k'} a_{j,k}^*(l) a_{j',k'}(m) \int \Phi_j^*(\mathbf{r} - \mathbf{R}_k) \times \Phi_{j'}(\mathbf{r} - \mathbf{R}_{k'}) d^3r \quad [21]$$

The Kohn–Sham Hamiltonian is given as in eqn [14]:

$$H^{\text{KS}} = \frac{-\hbar^2 \nabla^2}{2m} + V_p^{\text{ion}}(\mathbf{r}) + V_H(\mathbf{r}) + V_{xc}[\rho(\mathbf{r})] \quad [22]$$

The matrix elements can be computed directly if H^{KS} is specified. Otherwise, the matrix elements can be fit to experiment. Once the matrix elements are specified, the eigenvalue and eigenfunctions can be found using standard matrix operation packages.

Methods using local orbitals can be very efficient for nanostructures. If the local orbital expansion is restricted to a small number of orbitals, the size of the matrix in eqn [19] can be quite tractable.

Another option is to use a plane wave basis instead of a localized basis, such as a set of Gaussian orbitals. In the case of a plane wave basis, pseudopotentials play a crucial role. The pseudopotential can be expanded using a rapidly converging set of plane waves. Likewise, no cusps are present in the wave functions allowing a much smaller set of plane waves than would be sufficient to converge the all-electron wave function. The plane wave basis can be written as

$$\Psi_{n,k}(\mathbf{r}) = \sum_{\mathbf{G}} a_{\mathbf{G}}(n) \exp(i(\mathbf{k} + \mathbf{G}) \cdot \mathbf{r}) \quad [23]$$

$\mathbf{k}$ is a wave vector as for a Bloch state in a crystal and $\mathbf{G}$ is a reciprocal lattice vector. The reciprocal lattice vectors are defined by the size and shape of the crystalline unit cell. They are defined such that

$$\exp(i\mathbf{G} \cdot \mathcal{R}) = 1 \quad [24]$$

where $\mathcal{R}$ is a lattice vector.

A plane wave basis is a well-known and utilized instrument for calculating the electronic structure of crystalline matter. Methods based on a plane wave basis can be implemented for localized systems such as a quantum dot by retaining an artificial periodic system, for example, by placing the system of interest in a large unit cell, or supercell. Provided the cell size is sufficiently large, the solution of the problem results in the electronic structure of the isolated quantum dot. This method is very easy to implement and has been employed for systems of several thousand atoms. A significant complication concerns charged systems. In this case, the supercell is not neutral and the net charge on the system diverges. Compensating background charges are sometimes used to overcome this problem.

It is also possible to solve the Kohn–Sham equations without the use of an explicit basis. One approach is to solve the eigenvalue problem in real space where a grid serves the role of a basis. The real space method is highly advantageous over the plane wave method in a number of respects. Real space methods do not require supercells, and as a consequence, can be employed to examine charged systems without adding compensating backgrounds.

Real space methods for nanostructures are often based on a three-dimensional cubic grid. The Kohn–Sham equation can be discretized via a higher-order finite differencing procedure over the grid to yield

$$\begin{aligned} -\frac{\hbar^2}{2m} \left[\sum_{n_1=-M}^M C_{n_1} \psi_n(x_i + n_1 h, y_j, z_k) + \sum_{n_2=-M}^M C_{n_2} \psi_n(x_i, y_j + n_2 h, z_k) + \sum_{n_3=-M}^M C_{n_3} \psi_n(x_i, y_j, z_k + n_3 h) \right] \\ + [V_{\text{ion}}(x_i, y_j, z_k) + V_{\text{H}}(x_i, y_j, z_k) + V_{\text{xc}}(x_i, y_j, z_k)] \psi_n(x_i, y_j, z_k) = E_n \psi_n(x_i, y_j, z_k) \end{aligned} \quad [25]$$

where h is the grid spacing, $C(n_1, n_2, n_3)$ are coefficients for the finite difference, the summation is over M neighboring grid points, for example, if $M=1$, then standard finite differencing is used.

Real space methods can be utilized without a uniformly spaced cubic grid, but such implementations are more complicated, especially when used to compute interatomic forces. A uniformly spaced grid within a three dimensional is frequently used for nanostructures. Simple boundary conditions are employed, such as outside a spherical domain, the wave functions are constrained to zero. Special data structures are used to discard these points and keep only those having a nonzero value for the wave function. Iterative diagonalization methods, which can be made very efficient for sparse grids, are easy to implement for real space problems.

Calculated Electronic Levels in Nanostructures

Solutions of the Kohn–Sham equation can be used to describe the electronic structure of a variety of nanostructures such as nanowires, nanotubes, or quantum dots. In the case of nanowires or nanotubes, the structure is localized in two dimensions and often periodic in the third. In this case, Bloch wave functions can be used for the periodic structure. For quantum dots, supercells or localized domains can be utilized along with plane waves or grid methods.

In Figure 5, the evolution of energy levels are illustrated for GaAs quantum dots. The stoichiometry of the dots are $(\text{GaAs})_n \text{H}_m^+$. The H_m^+ notation refers to fictitious hydrogen-like atoms used to passivate any dangling or partially occupied bonds. In this example, the structure of the dots is taken to be that of a fragment of the GaAs crystal. For small dots such as $(\text{GaAs})_2 \text{H}_6^+$, the energy levels are well separated and the gap between filled and empty states is of the order of ~ 6 eV. Technically, this gap cannot be compared to the observed gap as these energy levels do not correspond to those created by an electron–hole pair. The Kohn–Sham eigenvalues have meaning only in solving for the total energy as in eqn [17]. However, more realistic approaches to excited state properties have validated the use of Kohn–Sham eigenvalues as a qualitative or, in some cases, a semiquantitative method of determining the optical gap.

As a function of cluster size, the size of the gap between empty and filled states decreases as the size of the cluster increases. This is illustrated in Figure 6 where the gap size is plotted versus the cube root of the number of GaAs units present. The cube root should

Figure 5 Energy levels of $(\text{GaAs})_n \text{H}_m^+$ quantum dots. The number of GaAs units is indicated in the figure. The highest occupied level is taken as the zero energy reference.

Figure 6 The energy gap in quantum dots of $(\text{GaAs})_n \text{H}_m^+$ vs. the size of the dot. The size of the dot is estimated by the cube root of the number of GaAs units in the dot. The curve is after eqn [6] with a scaling of R^{-1} , see text.

scale with the diameter of the quantum dot, provided a large number of atoms are present. The general trend of the gap with the size of the dot is consistent with eqn [6] with one notable exception. The scaling is not consistent with R^{-2} behavior, which would only be expected for a particle contained by an infinite well. Owing to the finite size of the quantum well in real systems, the scaling obtained from accurate calculations yields gaps that scale closer to R^{-1} as indicated in Figure 6.

A notable feature of the energy level spacings is the distribution of these states as a function of the dot size. For large systems, the distribution of the eigenvalues should approach the crystalline state. In Figure 7, the crystalline density of states is compared, that is, the number of states per unit energy, to the number of eigenvalues per unit of time for a large dot. The structure in the density of states can be attributed to the topology of energy bands. When the energy band is flat, that is, the derivative of the energy with respect to the wave function vanishes, the density of states possesses an identifiable structure. As a function of size, one would expect large clusters to possess similar structural features. The number of atoms in a dot required to reproduce bulk features of the density of states can be assessed through the direct calculation of the eigenvalue spectrum. In Figure 7, a comparison between the crystal and dot density of states for the dot, $(\text{GaAs})_{342} \text{H}_{192}^+$ is illustrated. The distribution of eigenvalue states matches the bulk density of states very well with one notable exception. Some states are associated with the fictitious hydrogens; these states have been removed from Figure 7. More complex nanostructures can be examined using similar approaches.

Figure 7 Densities of states for crystal gallium arsenide (bottom) and the eigenvalue distribution for $(\text{GaAs})_{342}\text{H}_{192}^+$ quantum dot (top). Extrinsic contributions have been removed from the plot.

Abstract

Terahertz (THz)-based science is growing rapidly thanks to its unique capability to investigate, excite and master degree of freedom in matter. In contrast to the existing thermal excitation mechanisms, which rely on high energy excitations, terahertz radiation, in resonance with low-energy excitations and quasiparticles, offers a non-thermal excitation pathway that is able to selectively populate excited states. In less than 10 years, scientists have made outstanding progresses in terahertz-based science and are now able to excite and control structural, electronic and spin dynamics that ultimately may result in phase transitions. Intriguingly, a terahertz-driven out-of-equilibrium configuration can reveal hidden states of matter, inaccessible in the static configuration.

Key points

- To guide the reader in the understanding of the unique capability of THz radiation to study and control degree of freedom in matter
- To describe the main sources for THz generation
- To describe equilibrium and out of equilibrium states in the THz range
- To describe resonant and non-resonant THz control of matter
- To describe actual example of THz-driven phase transitions
- To present a future outlook for the field of THz light and manipulation of matter

Introduction

Electromagnetic waves have provided extremely versatile stimuli for probing and exciting different degree of freedom in matter. Each time that the development of suitable sources and detectors have accessed new regions of the electromagnetic spectrum, its capability to manipulate degrees of freedom in matter has been exploited. In the same spirit, recent technological advances in the THz spectral range (defined here as approximately 0.1 THz to 30 THz) allowed for unexplored pathway to control matter. Importantly, THz waves are nonionizing and nonthermal. These unique characteristics make them suitable for identifying, probing and controlling a variety of material properties. In contrast to optical radiation (photon energy of the order of eV) predominantly interacts with valence electrons, THz radiation (photon energy of the order of meV) allows direct access to numerous low-energy excitations in condensed matter. The THz region encompasses a range of phenomena, including lattice vibrations, intraband transitions in semiconductors, spin waves, and internal excitations of bound electron-hole and electron-electron pairs. In addition

to a resonant coupling to such excitation, the strong THz fields now available also permit non-resonant control of magnetization and electron dynamics.

This chapter guides the reader through the wide field of *THz light and manipulation of matter*.

Section “*Perspective: From optical to THz control over matter*” start by giving a perspective overview of *optical* vs *THz* control over matter, focusing on the difference in the involved excitation mechanisms. This paragraph provides a reading key to interpret the fast-developing THz science in comparison to the well-established methods that make use of optical light.

Section “*THz sources*” describes the main sources of THz radiation available up to now, discerning between *weak* and *strong* THz sources.

Section “*THz light-matter interaction and experimental tools*” discusses the fundamental interaction mechanisms of THz radiation with matter. Particularly useful is to distinguish between the study of material properties at *equilibrium* and *out of equilibrium*. More attention will be given to this last aspect, being more related to the chapter topic.

In the same spirit, section “*THz control over matter*” concentrates on the capability of strong THz radiation to manipulate and control different degrees of freedom in condensed matter. Some fascinating examples of *resonant* and *non-resonant control* over the lattice, spin and electronic degree of freedom will be presented. It will be will point out how, in some cases, the delicate balance between different degrees of freedom brings the system on the edge of stability between different phases and the THz light drives highly nonlinear collective responses that may result in electronic or structural phase transitions and, intriguingly, can reveal hidden orders.

Perspective: From optical to THz control over matter

The energy of an optical photon (eV) is at least one order of magnitude higher than the energy scale of the main collective excitations in condensed matter systems. When dealing with optical excitation of matter, the extra energy results in highly incoherent dynamics, less control and unwanted temperature increase. In contrast, THz light (meV), being in resonance with them, allows for direct coupling to relevant low-lying excitations such as electron plasmas in metals, superconducting gaps, vibrational modes of the crystal lattice and magnetic excitations.

Given the possibility to target a certain resonance, the THz excitation path is mainly a mode-selective process that is inherently non-thermal in nature (i.e., it can be described as a redistribution of quasiparticle populations on a particular mode, in contrast to a thermal effect which equally distribute energy among all quasiparticles) (De la Torre et al., 2021).

Non-thermality and mode-selectivity have important consequences on the description of excitation pathway:

- (i) First, it is possible to overcome the simplified models that neglects nonthermal effects resulting from ultrafast light-matter coupling. It is indeed true that in many correlated systems, the notion of thermality, breaks down on ultrashort (femtosecond) to intermediate (subpicosecond) timescales (Abdurazakov et al., 2018)

In this sense, by means of ultrafast experiment triggered by THz radiation, it is possible to access processes dominated by dynamics that cannot be described by a hot electronic subsystem that thermalizes back to equilibrium through heat exchange with the cold crystalline lattice (phonons), i.e., modeled by the two-temperature models, (Anisimov et al., 1974) or microscopic three-temperature generalizations (Koopmans et al., 2010).

- (ii) Second, it is possible to investigate the cooperation of electrons and nuclei in dynamics that may occur beyond the Born-Oppenheimer approximation. More in general, one can overcome the assumption that the mutual couplings between degrees of freedom are not modified by the excitation. Indeed, whereas an electromagnetic wave in the optical range interact predominantly with electronic states and exert forces on the nuclei only indirectly, an electromagnetic wave in the THz range can drive electric-dipole active vibrational modes by exerting forces directly on the charged nuclei. As a consequence of the nuclear excitation, the electron-phonon coupling is modified and, in some cases, emergent electronic properties result from the excitation of the nuclear degree of freedom. This is a research line that goes beyond the Born Oppenheimer approximation, as it treats the electronic and nuclear degrees of freedom no more as separate systems. As we are going to discuss in the next chapter, the research field is strongly active, with ongoing exciting experiments which go hand by hand with theory (Johanson, 2022; Basini et al., 2022a,b,c; Appleby et al., 2022; Rodríguez et al., 2022).

THz sources

Terahertz sources showing high stability and covering a broad spectral range are nowadays produced in wide range of new technologies. The following paragraphs provide a list of the most common source available for generation of *weak* and *strong* terahertz radiation.

Weak THz sources

Photoconductive Antennas. To generate THz radiation by means of photoconductive antennas (PCA), a highly resistive direct semiconductor thin film with two electric contact pads is excited by an optical pulsed laser with pulse width < 1 ps and photon

energy larger than the semiconductor energy gap (Bacon et al., 2021). Each photon absorbed by the film creates a free electron in the conduction band and a hole in the valence band. The pair becomes then electrical conducting until the carriers are recombined, generating photons in the THz range. A PCA can be used as THz transmitter as well as THz receiver. In case of a *transmitter*, the excited carriers are accelerated by a voltage V connected on the electrical contacts resulting in a short broadband electromagnetic pulse. A number of semiconductor crystals are used for the sources: Si, GaAs, InAs, InP, and ZnTe. PCA sources can emit THz radiation in the bandwidth 0.1–4 THz (Katzenellenbogen and Grischkowsky, 1991), with an average radiation power of up to 40 μW (Zhao et al., 2022). In case of a THz *receiver*, an amplifier is connected on the electrical contacts and the excited carriers are accelerated by the electric field component of the incident terahertz leading to a voltage signal across the antenna gap.

Quantum cascade Lasers (QCL). QCLs are electrically pumped semiconductor lasers (Wen and Ban, 2021; Sirtori et al., 2013). Their operation mechanism exploits transitions in cascaded quantum well structures to generate terahertz radiation between 2 THz to and 5 THz. QCL emission frequency is determined by the size and width of the quantum wells and is independent of the materials used. The name quantum cascade laser is due to the number of emitted THz photon for each electron that goes through the quantum well (typically around 100, as the number of periods in the laser).

The limitation of QCL is in low operation temperature needed, i.e., the highest operation temperature realized to date is 250 K in pulse mode (Khalatpour et al., 2021).

Strong THz sources

Optical rectification. The main class of strong THz sources makes use of optical rectification of intense laser pulses in nonlinear media (Hoffmann and Fülöp, 2011), commonly DSTMS (Vicario et al., 2015), OH1 (Vicario et al., 2015), DAST (Schneider et al., 2006) and BNA (Shalaby et al., 2016) crystals. Optical rectification is a second-order nonlinear optical process, a special case of difference-frequency generation (DFG), where the spectral components from an optical laser pulse with duration sub-100 fs are mixed, generating a spectral component in the THz range. The conversion efficiency is limited by the phase mismatch between the driving laser, which propagates faster, and the generated THz pulse, which propagates slower. By tilting the wavefront of the driving laser, the phase velocity of the generated pulse can be equal to that of the driving pulse, enabling a huge increase in the generated field (Salén et al., 2019).

It is worth mentioning that the spectra of the generated THz is broad, covering a range of 0.5 THz–6 THz. Anyway, a narrowband could be preferred, for example if one needs to selectively access a particular excitation. In this case, (i) by changing the modulation period of the laser pump (Vicario et al., 2020), or (ii) by difference-frequency mixing of two linearly chirped near-infrared pulses in an organic nonlinear crystal (Liu et al., 2017), a frequency-tunable narrowband and intense THz field can be generated.

Spintronic emitters. Spintronic emitters consist of multilayer heterostructures of ferromagnetic and nonmagnetic layers, usually heavy metal (Papaioannou and Beigang, 2021). They generate THz radiation by means of a physical mechanism called inverse spin Hall effect (Kampfthaler et al., 2013a). Seifert et al., 2017 explored the up-scaling capabilities of metallic spintronic stacks in order to achieve intense THz sources.

Plasma based. Femtosecond-laser-induced plasma formation in gaseous and solid foil media is also a source of THz radiation. After the laser excitation, hot electrons are “blown” away from the foil leaving behind a strong electrostatic potential. This potential ionizes atoms, and the dynamics of an induced plasma leads to strong THz transients. Nowadays, electric field amplitude of 10 MV/cm can be reached, even if theoretical modeling shows that it is possible to achieve values up to 100 MV/cm ($\text{V}/\text{\AA}$) (Sun et al., 2022; Herzer et al., 2018).

Radiation from charged particles. When a charged particle moving with a constant velocity traverses an interface, an electromagnetic field in the THz range can be generated, known as transition radiation (Ginzburg and Tsytovich, 1979). In particular, the transition radiation from relativistic electron bunches passing through a metallic foil is used able to generate THz radiation, with electric field amplitude of the order of tens of MV/cm with a cutoff frequency limited by the inverse bunch duration. Given that electron bunches with kinetic energy of the order of GeV are needed to produce 10 MV/cm THz pulses, the availability of strong THz sources based on transition radiation is very limited. Only a few national laboratories in the world operate such sources (Salén et al., 2019).

Synchrotrons and free electron lasers. Synchrotron radiation (SR) is the type of radiation emitted by relativistic charged particles in an external magnetic field. The origin of SR lies in classical electrodynamics: whenever a charged particle is accelerated, the surrounding electric field distribution is distorted. Then, a fraction of the field detaches from the particle and constitutes a waveform of separate photons. Synchrotron are able to produce field strength of the order of 0.1 MV/cm.

In order to increase the pulse energy of synchrotron radiation, electron bunch deflected by a periodic magnetic field can be used (Mak et al., 2019). The emitted energy becomes N times larger compared to that from a bending magnet, where N is the number of oscillations performed by the bunch. Electric field amplitude of around 5 MV/cm can be achieved. Given that the bandwidth of the emitted THz is inversely proportional to the number of undulator periods, this type of sources generates very narrow bandwidth, which can be a limit for certain applications.

Recently, a new class of strong-field single-cycle sources based on the idea to enable constructive interference between broadband light waveforms emitted by different bunches has recently been proposed and studied theoretically (Tanaka, 2015; Kida et al., 2016; Goryashko, 2017).

THz light-matter interaction and experimental tools

Terahertz light has proven to be a fine tool to *probe* and *control* quasi-particles and collective excitations in solids, to drive phase transitions and associated changes in material properties (Koshihara et al., 2022; Irizawa et al., 2021; Salén et al., 2019; Dhillon et al., 2017; Nicolatti and Cavallei, 2016; Ferguson and Zhang, 2022). Weak terahertz sources are mainly used to study equilibrium states by means of spectroscopy methods (Neu and Schmuttenmaer, 2018; Lee, 2009). However, owing to recent developments in high-power sources, scientists have started to abandon the role of pure observers and are now exploiting intense THz radiation to engineer transient states of matter. Strong terahertz sources enable the study of out-of-equilibrium states by means of pump-probe techniques, able to resolve in time the evolution of the system after excitation.

To develop strategies for THz excitation and control of matter, it is helpful to consider the basic interaction mechanisms between THz light and matter. When a THz wave interacts with matter, the oscillating electric (E) and magnetic components (B) of the electromagnetic radiation exert a force on the ions and the electrons of charge q , in the Lorentz form of $F = qE + qv \times B$, where v is the velocity of the charged particle. The Coulomb term, proportional to E , induces an electric-dipole density (polarization) P , which is accompanied by an electrical current density dP/dt . At the large THz electric field amplitudes considered here, the relationship between P and E can become extremely nonlinear. The Lorentz force arising from the THz magnetic field B is usually neglected in equation, as it is smaller than the Coulomb force by a factor of v/c (where c is the speed of light in vacuum). However, as explained in details in paragraph 4, the magnetic field can exert a significant torque on magnetic dipole moments. The torque moment has the form of $\tau = \mu \times B$ and act on any magnetic-dipole moment μ in the solid (which is not parallel or antiparallel to B), such as the one carried by the electron spins.

Equilibrium

At equilibrium, THz radiation is an efficient tool to probe low-energy excitations with the unique capability to explore the material properties which have been inaccessible until recently. The result obtained experimentally correlates well with theoretical study showing that terahertz spectroscopy provides resonant access to the motions of free electrons, the vibrations of crystal lattices and the precessions of spins. In comparison with optical spectroscopy which requires spectrometers to resolve the response of the system, THz spectroscopy allows to characterize the complete electric field of a THz pulse, to yield full phase and amplitude information of the material response directly in time domain. The complex dielectric function of a sample in the beam path can thus be determined directly (Fattinger and Grischkowsky, 1989) without having to rely on Kramers-Kronig relations.

From the complex dielectric function in the THz range at equilibrium, it is possible to reveal the presence of dipole active phonons, magnons, and electronic plasma resonance. Particularly relevant is the study of the complex conductivity to identify a superconductive state. In this case, large increase in carrier mobility, accompanied by the opening of a gap in the real part of the optical conductivity is expected, whereas the imaginary part diverges at low frequencies due to the inductive nature of the response of superconducting carriers (Zimmermann et al., 1991).

Out-of-equilibrium

The emergence of collective order in matter is among the most fundamental and intriguing phenomena in physics. As explained in paragraph 1, THz radiation allows for a dynamical control and creation of novel ordered states of matter that goes beyond the simple melting of thermal states by laser-induced heating. In this sense, one has to consider non-thermality as a resource to exert control over materials on ultrashort timescales in a flexible and reversible manner. Fig. 1 (De la Torre et al., 2021) shows an illustration of the nonthermal pathways triggered by laser excitation as a function of growing excitation strength. The system coordinates, such as an electronic order parameter or a lattice displacement are displayed on the x-axis, the potential (or the free energy landscape) is displayed on the y-axis.

Fig. 1 Illustration of nonthermal pathways triggered by laser excitation. All panels show a potential or free energy landscape as a function of a system coordinate, such as an electronic order parameter or a lattice displacement. (a) Weak excitations around a stable minimum (ground state) permit one to probe collective modes and their mutual couplings. (b) With a short, more intense laser pulse, one can switch between degenerate ground states (A and B) or drive the material to a nonthermal, metastable excited state C. (c) Nonequilibrium critical behavior can be induced by a short, even more intense excitation that transiently modifies the free energy landscape itself. (d) With a strong excitation, the system can also be driven into anharmonic regimes with deviations from parabolic behavior, which allows one to probe nonlinear effects and change effective couplings in the material. (De la Torre et al., 2021).

Another class of nonthermal phenomena (not shown here) are those that occur for the duration of the laser pulse, where the microscopic degrees of freedom are strongly coupled to the amplitude, frequency, and polarization of the light field, in some cases forming dressed states that can be described by Floquet theory (Sono et al., 2022; De la Torre et al., 2021; Uchida et al., 2016).

In this sense, THz provides a unique strategy to investigate emergent phenomena with no equilibrium counterpart.

In order to study the out-of-equilibrium states described above, time-resolved techniques, such as pump-probe, are needed. In a pump-probe experiment, an ultrashort pump pulse of laser light triggers a process, and another ultrashort pulse interacts with the system and measures the transient change in the material response after a well-defined time delay. The dynamics induced by a THz pump pulse (usually in the picosecond timescale) are often monitored using a femtosecond probe pulses in almost any region of the electromagnetic spectrum (X-ray, ultraviolet, visible, infrared, or THz) thus accessing changes in the structural, electronic, or optical properties of the excited material. It is worth citing that within the study of out-of-equilibrium phenomena, the development of pump-probe techniques recently achieved the possibility to isolate responses which are purely nonlinear. To this aim, inspired by nuclear magnetic resonance spectroscopy, experimental works that make use of a double (or more) pump scheme. The ultimate nonlinear THz experiments rely on 2D-THz spectroscopy, which has the potential to observe the nonlinear response, typically to all orders. In such experiments, both pump and probe processes act in the THz regime, and the experiment measures the nonlinear component of the system response to the applied THz fields (Lu et al., 2018; Elsaesser et al., 2019).

THz control over matter

This paragraph provides an overview of how the electric and magnetic fields of intense THz transients can be used to control matter. An unprecedented degree of control over material functionality on the femtosecond timescale ($1 \text{ fs} = 10^{-15} \text{ s}$) will be discussed.

The electric and magnetic field amplitudes of existing strong THz radiation can exceed 1 MV cm^{-1} and 0.33 T , respectively. When such a pulse is incident on matter, it interacts with various degrees of freedom, and it offers a versatile way to control crystal lattice vibration, spins precession and electrons acceleration and excitation.

Some of the examples of THz control presented below take advantage of resonant coupling to some material degrees of freedom, thus allowing for coherent accumulation of the energy deposited by the driving THz field in a selected mode. In addition to such resonant manipulation, high-field THz sources allow a non-resonant control, as they can accelerate electrons to very high energies over just half a cycle of their driving field.

Resonant control

The energy of THz photons matches the fine energy structure of phonons, magnons in antiferromagnets and electron vibrations (i.e., Cooper pair in superconductors) thus allowing for a specific target and control on such excitations.

Control over lattice

The control of coherent lattice vibrations (i.e., phonons) is crucial to promote and tune several properties of matter. As will be shown later, the control of phonon frequencies and amplitudes allows the tuning of structural distortions, switching of ferroelectric and ferroelastic properties and in some cases, generation of a local magnetic field.

Traditionally, coherent lattice excitation by short light pulses has been obtained by optical femtosecond pulses in Raman scattering techniques (Zeiger and Dresselhaus, 1992; Merlin, 1997; Yan et al., 1985) where the coherent phonon modes are excited by scattering of the radiation via an intermediate electronic energy level. The vibration symmetry that can be controlled by Raman scattering is even, and the mechanism is not very efficient due to the non-resonant process and to the energy dissipation in electronic transitions. On the other hand, infrared (IR)-active phonons (i.e., odd symmetry) can be excited directly by means of a resonant THz field. The mechanism is extremely efficient and can lead to coherent atomic motions whose amplitude exceed the 10% of the unit cell dimension (Salén et al., 2019; Kozina et al., 2019; Nicolatti and Cavallei, 2016). When infrared (IR)-active vibrational modes are driven to large amplitudes, nonlinear coupling between infrared- and Raman-active modes can occur. There exist two distinct pathways: (1) the so-called nonlinear phononics effect of phononic rectification, alternatively called *ionic Raman scattering (IRS)* (Maradudin and Wallis, 1970; Wallis and Maradudin, 1971; Humphreys, 1972), in which the coupling occurs via the anharmonic lattice potential (Juraschek and Maehrlein, 2018; Nicolatti and Cavallei, 2016; Först et al., 2011b), and (2) the *infrared-resonant Raman scattering (IRRS)* (Khalsa et al., 2021). This last mechanism is governed by the nonlinear lattice polarizability, via a Raman-scattering mechanism mediated by the displacements of IR phonons. Both contributions exert a unidirectional force on the Raman coordinates and can lead to a change of crystalline symmetry, giving rise to opportunities for ultrafast control of functional properties of crystalline materials linked to symmetry.

A resonant drive of the lattice may also permit control of electronic properties such as conductivity. Of particular interest are many of the perovskite-type crystals with central ions having only partially filled d orbitals form complex correlated electronic phases. Phonons in these crystals have been resonantly excited with midinfrared ultrashort pulses, and in some cases, dramatic transient changes in the electrical conductivity have been observed as a result of coupling between the lattice and electronic degrees of freedom (Salén et al., 2019; Koshihara et al., 2022). Also, the topological properties of topological semimetals can be manipulated through lattice distortions. It was demonstrated that the THz light excitation of lattice displacements alters considerably the electronic structure of these materials, generating an interlayer strain with less lattice damage than uniaxial straining. It is worth to note that the possibility of an ultrafast manipulation of the topological properties of such materials opens the intriguing possibility to develop a topological switch in the THz frequency range (Sie and Lindenberg, 2019).

Control over magnetism

The magnetic degree of freedom (i.e., spin orientation and spin dynamics) of a material can be controlled by the magnetic field of an external THz transient by means of the so-called *Zeeman interaction*. An external transient magnetic field B can indeed exert a torque on the magnetic moments present in the material and causes a spin precession along its axis. In ferromagnets, collective spin modes typically exhibit frequencies lower than 100 GHz, in contrast to antiferromagnets whose resonant modes can easily reach the THz range. THz spin control of antiferromagnets indeed rely on the enhanced spin-light coupling at magnetic resonances, such as spin waves (magnons). Direct excitation has the advantage of minimal excess heat deposition, but is on the other hand very challenging due to the low magnetic-field strengths of currently realizable THz sources.

A prototype antiferromagnet where resonant magnon excitation has been achieved, is NiO (Kampfrath et al., 2011). Due to the relatively long lifetime of the spin wave (tens of ps), control of the dynamics was possible over an extended time window. Importantly, it was possible to switch off the spin precession almost entirely by using the torque of a second THz magnetic pulse arriving precisely 6.5 oscillation cycles after the first. An exciting future goal would be the use of arbitrary THz pulse sequences or pulse-shaping for nonlinear spin control.

Besides spin waves in antiferromagnets, THz radiation recently allowed the first direct experimental evidence of an intrinsic inertial spin dynamics in the form of nutation of the magnetization vector in a ferromagnet, i.e., intrinsic oscillations of the axis during precession, which occurs at frequency of approximately 0.5 THz (Neeraj et al., 2021). The terahertz magnetic field acts here as a driving periodic force, to which the magnetization responds, revealing the presence of underlying resonance (nutation) THz superimposed on the purely off-resonant, forced response of lower amplitude (precession induced by the torque).

Importantly, the temporal evolution of the nutation after THz excitation revealed that its resonance frequency is intimately related to the magnetocrystalline anisotropy (Unikandanunni et al., 2022a).

Finally, a new interesting possibility for controlling magnetism is offered by multiferroics materials, where the coexistence of electric and magnetic order result in the presence of electromagnon, a mixture of phonons and magnons that exhibit both electric and magnetic dipole moments. A resonant electric field in the THz range can couple to such the electric dipole which, in turn, modify the magnetic structure of multiferroic. In this case, the spin motion is indirectly driven by the electric field, and the delay between THz pump and sample response corresponds exactly to half of a single oscillation cycle. Remarkably, the efficiency of the driving mechanism was more than an order of magnitude larger than that expected for spin precession driven directly by the magnetic-field component of the THz pulse (Kubacka et al., 2014; Pimenov et al., 2006), revealing the great potential of multiferroic materials for this kind of application.

Phonomagnetism and magnetophononics. Spin-lattice interaction makes it possible to use phonons as the intermediary between the laser pulse and the magnetic order. In this sense, resonant phonon excitation can be used to coherently manipulate macroscopic magnetic states (Juraschek et al., 2020). For example, THz activated spin-lattice interactions causes the generation of magnetization in antiferromagnets (Disa et al., 2020; Baier et al., 2016) or a magnetization switching in ferromagnets (Afanasiev et al., 2021; Li et al., 2013). In antiferromagnets, is also possible to excite a spin precession (magnons) driving a circular dynamic in the lattice. The lattice rotation causes a breaking of time-reversal invariance and mimics the application of a magnetic field (Nova et al., 2017). On the other hand, it is true that, if driven coherently in a circular path, a phonon may itself carry a magnetic moment (Juraschek and Spaldin, 2019). Juraschek and Spaldin, 2019, the first experimental evidence of a phonon-associated magnetic moment was revealed by a circularly polarized THz electric field in a non-magnetic material (Basini et al., 2022a). This mechanism, named as dynamical multiferroicity (Juraschek et al., 2017) underlines the THz capability to reveal hidden orders in matter.

In all the above-mentioned studies, the transfer of energy is directed from phonons to magnons. The dual mechanisms, in which the transfer of energy is directed from magnons to phonons, is also possible. Anyway, photon-magnon coupling tends to be weaker than photon-phonon coupling, and photon-to-magnon-to-phonon system would require a more efficient coupling mechanism between the different quasiparticles (Juraschek and Narang, 2021). This is the case of the prototype antiferromagnetic compound cobalt fluoride (CoF_2), where a THz-driven efficient coupling between magnons and phonons was recently demonstrated (Mashkovich et al., 2021). The material hosts a magnon that couples its spin precession to the magnetic field of the THz light and in turn generates coherent structural oscillations corresponding to a Raman active phonon mode through a previously unknown energy-transfer mechanism and with unprecedented efficiency. The Raman mode is again coupled to the electron orbits and the magnetization of the bulk material.

Control over superconductivity

We now turn to electronic degrees of freedom. Because electrons have a much larger charge-to-mass ratio than ions, they are expected to exhibit a more pronounced nonlinear response to strong THz pulses (see also next chapter). Resonant THz control has been applied to the weakly bound electronic states of superconducting condensates, the so-called Cooper pairs, which are characterized by typical binding energies in the single-THz range (~ 10 meV). Selective breaking of these pairs by intense THz transients was possible in the classical BCS superconductor NbN (Matsunaga and Shimano, 2012) where the quenching of the superconductive state was observed. Moreover, Cuprate superconductors support so-called *Josephson plasmons*, that is, wavelike excitations of the Cooper-pair density oscillating at a frequency of several THz. Such a plasmon can also be resonantly driven by a strong THz wave, resulting in highly nonlinear dynamics. Another remarkable result achieved upon THz driving is the observation of radiation-enhanced superconductivity (Beck et al., 2013; Mankowsky et al., 2014, 2017). As it will be shown in the paragraph dedicated to THz-driven phase transition (4.C), THz allows not only to tune, but also to induce superconductive properties (Fausti et al., 2011; Mitrano et al., 2016).

Non-resonant control

In addition to the resonant excitation of coherent phonons and magnons, high-intensity THz pulses can also manipulate matter by depositing significant amount of energy into non-resonant degrees of freedom (Kampfath et al., 2013b). This can be done either through the magnetic field component of the THz pulse or through the electric field component. In this section, we demonstrate the non-resonant control of magnetization and electron dynamics using THz electric/magnetic fields with a few examples.

Control over magnetism

Coherent magnetization dynamics. Magnetic field component of THz pulse can exert Zeeman torque on the magnetization of ferromagnetic materials driving coherent precessional dynamics (Vicario et al., 2013). This dynamics is accurately described by the Landau-Lifshitz equation. For small deviation of magnetization from equilibrium, Landau-Lifshitz equation has the following analytic solution: $M(t) = \gamma \sin \theta \int H_{\text{THz}}(t) dt$ where M is the magnetization, H_{THz} is the THz magnetic field, θ is the angle between M and H_{THz} , and γ is the gyromagnetic ratio. From the equation it is clear that the exerted torque is maximum when M and H_{THz} are perpendicular to each other and zero when they are parallel (Bonetti et al., 2016). Coherent magnetization precession driven by the torque exerted by THz magnetic field has been suggested as a potential mechanism for ultrafast, non-thermal magnetization switching (Polley et al., 2018; Hudl et al., 2019).

Incoherent ultrafast demagnetization. In addition to the THz magnetic field-driven coherent precessional dynamics, the THz electric field can also trigger an ultrafast, incoherent demagnetization process. During this process, the material's magnetization is partially quenched within the duration of the pump pulse. In some cases, it is followed by the non-resonant excitation of the ferromagnetic resonance (FMR) on slower nanosecond timescales. The process of ultrafast demagnetization is caused by the energy deposited by THz pump to the non-resonant electronic degrees of freedom and is identical to the optically-driven ultrafast demagnetization (Chekhov et al., 2021). In orientations where both coherent and incoherent processes can occur, incoherent demagnetization dominates at high THz fields due to its quadratic dependence on the electric field amplitude.

Magnetization switching. Ultrafast, non-thermal magnetization switching using intense THz magnetic fields has been challenging due to the weak interaction between the THz magnetic field and the sample magnetization. In addition, for metallic ferromagnets, the incoherent electronic heating caused by THz electric fields can result in irreversible changes in the material (Shalaby et al., 2018). However, there are ways to overcome these challenges and achieve ultrafast, non-thermal magnetization switching. One approach is to enhance the THz magnetic field while minimizing the electric field, which can be done using metamaterial structures (Polley et al., 2018). Another approach is to isolate the THz magnetic field from the electric field by using azimuthal THz fields with spatially-isolated magnetic fields (Sánchez-Tejerina et al., 2022). Both of these methods can enhance the Zeeman interaction and reduce incoherent heating, enabling ultrafast, non-thermal magnetization switching.

Control of electron dynamics

Intense THz pulse with peak electric field of the scale of MV/cm can accelerate electrons to kinetic energies as high as a few eVs. The work done by the THz electric field on an electron of charge e and effective mass m^* within an optical half cycle is estimated by the pondermotive energy U_p expressed as,

$$U_p = \frac{e^2 E_{\text{max}}^2}{4m^* \omega^2}$$

where E_{max} is the peak electric field amplitude and $\omega/2\pi$ is the central frequency of the THz pulse. For example, an electric field of peak strength 1 MV/cm and central frequency of 1 THz can accelerate free electrons in vacuum to an energy of approximately 3 eV within a radiation half-cycle. Such an acceleration of electrons in material medium can in some cases even result in processes such as impact ionization and field emission of electrons. Here, we provide a few examples of non-resonant control of electron dynamics using THz electric fields possessing large pondermotive energy.

High-field carrier generation. Intense THz electric fields can generate charge carriers in semiconductors through two mechanisms: impact ionization and interband tunneling. In impact ionization, conduction electrons are accelerated by the THz electric field, leading to the excitation of valence electrons to higher conduction states through inelastic scattering. This process results in an avalanche of free electrons and an increase in the free-carrier density. For example, in the narrow-band gap semiconductor InSb, the free-carrier density increased by 700% following THz electric field excitation at an amplitude of 100 kV/cm (Hoffmann et al., 2009). The second mechanism, interband tunneling, involves the promotion of valence electrons to the conduction band through quantum-mechanical tunneling in the presence of an intense THz electric field. The rate of tunneling is greatly influenced by the rate at which decoherence occurs between valence and conduction band states, which is influenced by the lattice temperature. This results in a temperature-dependent carrier generation, unlike impact ionization, which is not directly affected by temperature (Kuehn et al., 2010a). In addition to these incoherent carrier generation mechanisms, intense THz electric fields can also cause coherent ballistic transport of electrons along the conduction band (Kuehn et al., 2010b; Houver et al., 2019).

Field emission. Intense THz electric fields can drive ultrafast emission of electrons through the tilting of the vacuum potential, allowing for the tunneling of electrons from the surface to the vacuum (Lange et al., 2020). Field-driven electron emission is preferred when the dimensionless Keldysh parameter γ_k is significantly smaller than one (Keldysh, 1965). This parameter is defined as $\gamma_k = \omega \sqrt{2m\phi} / eE_{\text{loc}}$, where $\omega/2\pi$ is the central frequency of the THz pulse, E_{loc} is the local electric field amplitude, ϕ is the work function of the metal, and e , m are, respectively, the charge and the mass of the electron. From the expression for Keldysh parameter

it is evident that field emission is likely to occur when THz fields have high electric field strength and low frequency, or in other words, when they possess a large pondermotive energy. In most observed cases of THz electric field-driven electron emission, a local field enhancement is required to push γ_k into field emission regime. This is achieved through the use of engineered metasurfaces, metallic nanotips or nanometer-scale surface inhomogeneities (Li and Jones, 2016; Unikandanunni et al., 2022b).

Franz-Keldysh effect. Intense THz electric fields can induce ultrafast changes in the conduction/valence bands of a semiconductor. These induced changes include absorption below the band edge, oscillatory behavior of the absorption above the band edge, and an absorption edge blue-shifted by U_p of the driving electric field. This *terahertz-dressed electronic state* can non-linearly interact with near bandgap optical probe (frequency, Ω_{NIR}) to emit optical sidebands of frequency $\Omega_{\text{NIR}} \pm 2n\omega_{\text{THz}}$ (Nordstrom et al., 1997).

The Franz-Keldysh effect can be divided into two regimes: the static Franz-Keldysh effect and the dynamical Franz-Keldysh effect. The static Franz-Keldysh effect occurs when the pondermotive energy of the electric field is larger in magnitude compared to the photon energy. In this case, the conduction and valence bands can adiabatically follow the applied low frequency THz field. The dynamical Franz-Keldysh effect, on the other hand, is characterized by a pondermotive energy that is comparable to the photon energy. In this case, the conduction and valence bands are unable to adiabatically follow the applied high-frequency THz field (Novelli et al., 2013).

Phase transitions and hidden orders driven (resonantly and non-resonantly) by THz light

Strong THz excitation lead to the observation of a broad variety of dynamical phenomena ending in a phase transition or revealing orders that are hidden in the static configuration at equilibrium (Koshihara et al., 2022; Aeppli et al., 2020). Compared with other phase transition schemes, light illumination has great advantages, such as its non-contact nature and easy tunability.

In THz-driven phase transition, the dynamics of the ground state or its mode-selective excitation, become accessible and act as a fuse for:

Structural phase transitions. An orthorhombic-to-monoclinic and centrosymmetric phase induced by strong THz pulses was observed in a Weyl semimetal (i.e., tungsten ditelluride) (Sie and Lindenberg, 2019).

Insulator-to-metal phase transition. Resonant THz-excitation of a phonon mode in a magnetoresistive manganite drives a non-equilibrium transition from a stable insulating phase to a metastable metallic phase (Rini et al., 2007; Iwai, 2012). Non-resonant THz-driven, insulator-to-metal transition was also shown in vanadium dioxide (Li et al., 2012; Gray et al., 2018).

Magnetic phase transition. Melting (Baldini et al., 2018), driving (Först et al., 2011a) or switching (Stupakiewicz et al., 2021) of magnetic order can be driven by THz radiation. Even more fascinating are recent evidence of THz-driven antiferromagnetic-to-ferromagnetic phase transition (Disa et al., 2020) and THz-driven dynamical multiferroicity (Basini et al., arXiv), this last occurring in a nonmagnetic and paraelectric material, i.e., SrTiO₃.

Ferroelectric Phase transition. It is possible to use terahertz fields to drive the ions into a new the positions that drive the crystal into a metastable ferroelectric phase, that do not exist in the phase diagram of the material and that can persist for many hours (Nova et al., 2019; Li et al., 2019; Subedi, 2017).

Superconductive phase transition. Light in the high THz range can be used to dynamically perturbed the non-superconducting phase in cuprates, allowing for the emergence of a transient superconducting state at temperatures where the non-superconductive phase is the ground state of the system (Fausti et al., 2011; Mitran et al., 2016). It is worth to note that, excitation in the visible range has already been used in the past to enhance, superconductivity (Nieva et al., 1992). However, the enhancement could be achieved only after the relaxation of hot incoherent carriers back to the ground state and was not triggered directly by the light field.

Topological Phase transition. The possibility to develop of an ultrafast manipulation of the different phases of a topological material was recently studied, only theoretically (Zhou et al., 2021).

Conclusion

In this chapter, we discussed on THz light-matter coupling as promising approach for the creation and control of material properties on an ultrafast timescale. These advances rely on an unprecedented range of optical excitations to probe and excite different degree of freedom. THz can indeed induce thermally inaccessible states which may lead to phase transitions, being a promising route to achieving nonequilibrium new functionality. By means of THz light, we are now able to create metastable states, but we are still far from mastering them. A better understanding on the coupling to the other environmental degrees of freedom and on the role of dissipation channels, is needed. The final aim would be a clever use of the energy dissipation processes with respect to the material functionality.

As more laboratories with strong terahertz sources will develop, the already active research field is expected to expand quickly. In this framework, theoretical and computational work plays a crucial role in the fundamental understanding and description of these emerging phenomena, allowing for prediction of new physical mechanisms and materials in which to find them (Juraschek et al., 2021, 2020; Vega et al., 2020; Fechner et al., 2018; Gu and Rondinelli, 2018). Finally, given the multidisciplinary skills needed in this field, a common language and concepts still need to be developed with the goal of unifying themes and contextualize THz control within the new field of ultrafast science.

Abstract

This chapter shows how full-scale experiments have contributed to the development of seismic metamaterials. The link between theoretical seismic cloaking and vibrational energy capture is presented. These theoretical concepts were borrowed from transformation optics and applied to geosciences and towards construction thanks to experiments carried out in full scale in summer 2012. The current nomenclature of seismic metamaterials has grown up and allowed for the emergence of the concept of meta-cities and auxetic materials for buildings.

Key points

- Emergence of seismic metamaterial.
- New concepts and challenges in soil dynamics and earthquake engineering.
- Perspectives for smart cities.

Introduction

In Civil Engineering, the high density of shallow and deep foundation or ground reinforcement techniques for buildings (Fig. 1), have led wave physicists to believe in a significant interaction of these buried structures mainly with surface Rayleigh waves propagating in low velocity soil (Fig. 2). As it transpires in Fig. 1, foundations for buildings can be modeled as periodic structures for which it has long been known that so-called stop bands can exist. Stop bands ("band gaps") underpin notably the physics of semiconductors. However, stop bands are also associated with intervals of frequencies for which waves are disallowed to propagate in a periodic medium (John, 1987; Yablonovitch, 1987; Markos and Soukoulis, 2008; Craster and Guenneau, 2013; Deymier, 2013). Applied to the building foundations in Fig. 1, the concept of elastic stop bands allows physicists to predict that surface ground vibrations of certain frequency ranges would be reflected, and this might be a way to protect the building erected atop these foundations from surface Rayleigh and Love waves. However, elastic waves originating from a source located underneath these foundations would still be able to hit the building since these foundations present a periodicity in the horizontal plane only. It is then tempting to draw analogies with the theory of metasurfaces and gratings in optics. On the other hand, a periodic structure in all three directions of space such as that proposed in John (1987) and Yablonovitch (1987) to control electromagnetic waves, may reflect elastic waves for all polarizations coming for all directions. It seems however unlikely that modern civil engineering techniques can structure the soil in all three directions proceeding for instance as is done with 3D printing technology.

Fig. 1 illustration of a real case of a large scale metasurface consisting of shallow square foundations arranged in a 2D periodic square mesh (Courtesy of S. Brûlé).

Fig. 2 Illustration (cross-sectional view in the $x-z$ plane) of the principle of seismic site effect (left) and seismic testing device (right) with photos of the periodically structured soil made of a 7×7 m grid of 2 m diameter self-stable holes in Saint-Priest near the French city of Lyon. The large scale experiment conducted in Summer 2012 is a proof of concept for a seismic flat lens via negative refraction of surface Rayleigh waves (Brûlé et al., 2017). P, S_H , and S_V waves are respectively, pressure, horizontal shear and vertical shear waves.

In §1, we recall the essential assumptions about earthquake engineering and soil dynamics, enabling us to draw an analogy with electromagnetism (§2); §3 illustrates the existence of large-scale structured media in urban areas, and §4 shows soil models for wave propagation in structured soils; §5 and 6 review the reasons for the emergence of seismic metamaterials and their classification. §7 reminds us of the importance of measuring on real, full-scale models and §8 opens the discussion on emergent topics.

Seismic wave amplification and seismic site effects

In earthquake engineering, the trapping of seismic waves in natural u-shaped basin filled with very soft sediments remains a major issue. The 1985 and 2017 earthquakes in Mexico City were devastating since this city was erected on a former drought lake (Bard and Bouchon, 1985; Bard et al., 1988; AFPS, 2018). Basically, we are looking for kinematic site effects, i.e. the amplification of the seismic signal in “soft” soils located a few tens of meters deep below the earth’s surface. These amplifications,

if they are not well anticipated due to insufficient knowledge of the geology, can seriously damage the buildings resting on the surface. The velocity of seismic waves is low in these soft soils. For example, the shear wave velocity V_s may be less than $300 \text{ m} \cdot \text{s}^{-1}$ even $100 \text{ m} \cdot \text{s}^{-1}$.

Shear waves (S-waves) are of particular interest in earthquake engineering because they contribute to the rocking motion of buildings, and concrete structures are sensitive to bending and shearing. However, Rayleigh waves (R waves), propagating in sedimentary basins filled with soft soils, are of real interest because the ground motion associated with R waves also has a horizontal component. In this article, we discuss more specifically the case of R waves.

In soil dynamics, the design is necessarily conservative because the goal is the safety of people during earthquakes. It is worth noting that the design of the deep foundations is often carried out in pseudo-static conditions. Thus, frequency effects are not highlighted in the same way as with a seismic metamaterial approach. The interest of the metamaterial approach lies in the description of additional complex wave phenomena in structured soils: filtering, polarization, etc.

Elasticity hypothesis for soils and analog approaches

For shear strain ranging γ from 10^{-6} to 10^{-4} , the constitutive law for soil is elasticity (Brûlé, 2023). Once we have explained the properties of poorly consolidated soils, it is easier to explain that much stiffer inclusions (steel, concrete, wood, etc.) or voids in the soil can interact with seismic waves. Young's modulus of concrete is 1000 times greater than that of soil. These two conditions allow us to seek analogies with other areas of physics.

The seemingly disconnected concepts of photonic crystals (John, 1987; Yablonovitch, 1987) and metamaterials (Smith et al., 2004; Anantha Ramakrishna and Grzegorzczuk, 2008) belong to the nano-scale world and electromagnetism. Typically, photonic crystals and metamaterials refer to periodic arrangements of elements with size comparable or much smaller than the considered wavelength (typically hundreds of nanometers for optical wavelength) that acquire effective properties of materials with unusual properties or applications such as negative optical index for a flat convergent lens (Veselago, 1968) with subwavelength resolution (Pendry, 2000), or highly anisotropic materials such as hyperbolic metamaterials or invisibility cloaking devices (Pendry et al., 2006). It might come as a surprise that one can mitigate surface Rayleigh waves in geophysics in a way like what physicists do for surface electromagnetic waves in optics and plasmonics.

It is this story that we want to tell in this chapter. Indeed, researchers in photonics who have made research advances in electromagnetic metamaterials and plasmonics have created a pathway for an enhanced control of unwanted ground vibrations induced by urban traffic, human activities, and seismic waves.

Amazingly, some experiments on extraordinary transmission of light through nanoholes in metals (Ebbesen et al., 1998) and even on broadband cloaking of spoof plasmon polaritons on metal surfaces structured with TiO_2 at the nanoscale (Renger et al., 2010) can be translated to the realm of seismic metamaterials at the meter scale (Brûlé et al., 2014, 2017). We point out that drawing analogies between surface Rayleigh waves in geophysics and spoof plasmon polariton in plasmonics makes it possible to envision seismic cloaks and carpets at the decameter and kilometer scales. Research advances in photonics and plasmonics in the past 20 years might lead to a paradigm shift in earthquake engineering in the near future. However, we are not quite there yet. Much remains to be done to overcome theoretical and practical obstacles, among which is the highly heterogeneous nature of soil, as can be inferred from the photos in Fig. 2 (MetaMAT's 10th webinar S2—<https://www.youtube.com/watch?v=HkikTHPEaQY>).

Real case study of a full-scale structured ground

One wonders whether there are any real cases of structured ground. Large-scale 2D structures have been shown to exist in urban environments (Brûlé, 2023). This is one of the interesting aspects of research in seismic metamaterials i.e., to identify existing structures and to study how they interact with elastic waves in light of the theory of locally resonant metamaterials. Here, the phenomenon of stop bands can occur at ultra-low frequencies, and this allows one to mitigate elastic waves of very large wavelength compared to the periodicity of the structure. This is the case of underground quarries exploited with a periodic geometry of cavities and pillars, which also interests us (Fig. 3a and b).

Moreover, urban soils are already so structured by underground installations (metro, trains, sewers, etc.) that, in some cases, the soil has been heavily substituted. We can no longer speak of wave propagation in homogeneous soil. This real ground should be considered when modeling wave propagation.

Defining a periodic soil model

There are several ways of describing wave propagation in a periodic medium consisting of soft soil with rigid elements. Here we illustrate the plane-wave case for S and R waves passing through an artificial device. We propose a mass and spring 1D model and a 2D diffraction model for R and S waves respectively.

Fig. 3 Top view of an underground quarry near Paris (France) (a). Cross section of the quarry (b).

1D soil model for Rayleigh waves

Fig. 4 simply illustrates the interaction of shallow square inclusions buried in the soil, with a Rayleigh wave. The ground motion at the surface can have been modified by the propagation of the waves in a new equivalent medium made of soil and inclusions and described by equivalent properties (equivalent density ρ_{eq} , equivalent shear modulus G_{eq}). In very soft soil, we can also describe the wave-matter interaction by the frequency effects obtained by modeling the inclusions and the ground as a diatomic chain (Fig. 5). This canonical example illustrates the complexity of wave phenomena involved in surface soils.

By examining the motion of three-square foundations submitted to a monochromatic Rayleigh wave, we note that the area of interest for observing relative motion corresponds to a spacing $a < \lambda_R$. Footings distant from λ_R vibrate in phase. In Fig. 4, for boxes e to h, the shear wave velocity $V_s = 200$ m/s leads to a wavelength of the order of 18 m, for a frequency of 15 Hz. We are interested in the relative motion between the foundations. The three footings shown are 1 m wide and the spacing is $a = 4$ m. For models with masses and springs, the challenge lies in the relevance of horizontal stiffnesses.

This example illustrates the complexity of wave phenomena involved in surface soils. For this case we have illustrated what is called the modification of the kinematic effect. Of course, in the case of a building, it is also necessary to consider the interaction of the foundations with the structure which is itself a periodic structure most often.

Fig. 4 Illustration of the depth of influence of Rayleigh waves on the soil motion $u(x, z)$ for inclusion of length p (boxes a to d correspond to four representative time-steps). Here the ratio Rayleigh wavelength over p , $\lambda_R/p = 5.7$ and the Poisson ratio $\nu = 0.45$. Top view of differential horizontal motion $u(x, z = 0)$ of three square inclusions spaced by $a = 5$ m. Here $\lambda_R/a = 4.7$ and $\nu = 0.33$ (boxes e to h correspond to the four time-steps of boxes a to b in left panel).

Fig. 5 1D diatomic model (masses m for foundation and M for soil). Horizontal stiffness is $K = K_x$. The parameter a is the spacing between two masses M or m . $F(\omega)$ is the harmonic force applied at one end of the model.

2D soil model for shear waves

For the case of shear waves S arriving at the surface with an angle i with the vertical axis z (Fig. 6a), it is the apparent velocities v_{app} and wavelengths λ_{app} that will concern the foundations for the study of horizontal motion (Fig. 6b). The most advanced case study is indeed the performance of a full-scale Fresnel lens (Fig. 6c).

Emergence of seismic metamaterial in earthquake engineering

Léon Brillouin (1946) emphasized that “All waves behave in a similar way, whether they are longitudinal or transverse, elastic or electric” (Brillouin, 1946). On the basis of this sentence, there are two paradigm shifts that have influenced the emergence of seismic metamaterials (Brûlé, 2023). The first one is conceptual and concerns the mechanical system studied (soil, buried foundations, buildings) with acceptance of the richness of its vibratory identity. The second one coincides with the idea that measuring signals experimentally illustrate the diversity of wave phenomena (Brûlé et al., 2014, 2017).

The first paradigm shift is based on a more in-depth study of diffraction phenomena at the scale of elementary objects, including metric size, and on taking into account the individual (local resonances) and group properties of all these objects considered as free oscillators or damped oscillators located on the surface or inside the ground. The use of diffraction is realistic because the superficial soils, few tens or even hundreds of meters thick, offer low shear wave velocity, less than $800 \text{ m} \cdot \text{s}^{-1}$. Due to these speed ranges and the identified frequency content (a few Hz), the seismic wavelengths are from a few tens to hundreds of meters, i.e., of the same order of magnitude as the characteristic lengths of surface structures.

The second paradigm shift lies in the search for the specific modal signatures of all these objects (structured soils, foundations, etc.), which requires the implementation of specific material means in the field (seismic sensors, sensor density, etc.) and also analysis tools to extract the data of interest. The transposition of the principles of periodic media to materials as specific as terrestrial materials requires rigorous definition of the validity conditions (Brûlé, 2023). In particular, these conditions are the strain range of the soil making possible the justification of an elastic behavior and a thick and homogeneous sedimentary site to limit the reflection effects of the underlying geological layers of contrasted impedance. The interpretation of the measurements is carried out from the perspective of the physical phenomena expected in periodic media. The seismic lenses tested (Brûlé et al., 2014, 2017) are explored as phononic crystals and metamaterials. By the effects observed, we point out the diffraction including Bragg reflection and double image of the source as a result of the negative refraction of a flat lens. However, a metamaterial is defined as an artificial composite material made from the assembly of resonators of smaller dimensions, whose wavelength at resonance is much larger than their physical dimension. These possibilities of local resonances are verified for Helmholtz resonators or very soft soils with rigid inclusions. On a macroscopic scale, a metamaterial is likely to exhibit properties that are not found in nature, such as negative refractive index. In addition to these early interpretations, there is an analysis of the modification of the polarization of surface waves. This new reading of the data opens the discussion on other descriptions of phenomena such as the existence of local resonances of rigid elements placed in a soil, and no longer of empty cylinders, as well as on static or dynamic homogenization approaches, dynamic anisotropy, transformational optics, surface resonators, etc. The modification of the signal by the fact of a structured soil and surface resonators are the link with Civil Engineering and the soil-structure interaction practiced in Earthquake Engineering. Research subjects converge in seismology and on the effects of secondary sources generated by surface buildings.

(b) Illustration of the phase difference for each element of a set of shallow foundations. (c) Application to the case of the Fresnel cloak consisting of many elements within a ring surrounding a protected area.

Main classification of seismic metamaterial

We can affirm that after a decade, three types of seismic metamaterials (Fig. 7) have emerged in scientific publications (Brûlé et al., 2020): “Seismic Soil-Metamaterials” (SSM), “Buried Mass-Resonators” (BMR) and “Above-Surface Resonators” (ASR). A few authors have suggested an intermediate concept between pure seismic isolators and devices located at foundation level. The device is then designed with the metamaterials tools (Casablanca et al., 2018; Xiang et al., 2012; Brun et al., 2011). There are good prospects for SSM because the process is capable of producing large quantities of elements in the soil, and ASR, especially if their effects can be coupled. In parallel, new possibilities to dissipate the seismic energy in the superstructures themselves are emerging thanks to the contributions of auxetic materials (Ungureanu et al., 2015; D’Alessandro et al., 2018). Let us further stress that SSM and ASR need not be periodic structures, e.g., the concept of graded metamaterials whereby the elementary cells can vary smoothly spatially (thus generating an almost periodic structure), first applied to the rainbow trapping effect for light (Tsakmakidis et al., 2007) has led to the concept of seismic rainbow to convert surface Rayleigh waves in harmless downward propagating shear volume waves: In Palermo et al. (2016), a seismic rainbow that falls in the category of SSM consists of spatially graded vertical subwavelength resonators, whereas its ASR counterpart consists of trees of varying height in Colombi et al. (2016).

In situ measurement: The key solution for understanding complex phenomena involved with seismic metamaterials

Reminder of the assumptions of the propagation medium: Superficial soil

Seismic waves propagate in a 3D elastodynamic medium. The seismicity is moderate, and we are in the far field, i.e., not close to an active fault zone. As the measurements are made in sedimentary basins, the sediments can be under consolidated and with a high-water content due to the presence of the water table at a shallow depth. For experiments, sources and sensors are located at the surface. Only the dynamic response recorded at the surface interests us. The soil is assumed to behave elastically under seismic disturbance.

The real soils are not homogeneous most of the time but stratified. However, the impedance contrasts between two successive soils are not high enough to create a powerful reflector at low depth. In fact, such a reflector would alter the signal collected at the surface due to a first arrival of a reflected wave mixing with the direct signal. The magnitude of seismic ambient noise can be high but the artificial source generates a much higher energy. For the demonstration, the source used is a punch ponder of 17 t, falling 20 m. The technology is the dynamic compaction for ground densification of 5–10 m thick soils. Clearly it is an impact source at the Earth’s surface. This allows us to continue the discussion on Green’s functions.

Interest of Green’s functions for elastodynamics in the case of structured soil

The Green’s function $G_{nk}(x, t; x', t')$ equates to the displacement response $u_n(x, t)$ of an elastic medium to a unit delta function force δ :

Fig. 7 Categories of seismic metamaterials as first proposed in Brûlé et al. (2020). Seismic-Soil Metamaterial in the upper left panel may consist for instance of boreholes (Brûlé et al., 2014) or concrete columns. Buried Mass-Resonators in the upper right panel have been proposed in Finocchio et al. (2014), with a further chiral twist in Achaoui et al. (2016), and are reminiscent of the diatomic chain in Fig. 5. Above-Surface Resonators in the lower left panel may consist of forest of trees (Colombi et al., 2016) or buildings (Guéguen et al., 2000; Housner, 1957; Wirgin and Bard, 1996). Auxetic Materials in the lower right panel are described by a negative Poisson ratio (Milton, 2002) and have been proposed as smart foundations in Ungureanu et al. (2015).

$$F(\mathbf{x}, t) = \delta(\mathbf{x} - \mathbf{x}')\delta(t - t')\mathbf{e}_k \quad (1)$$

in the $\mathbf{e}_k$ direction at location $\mathbf{x}'$ and time t' . In the case of homogeneous isotropic elastic medium with Lamé parameters λ and μ , this implies:

$$G_{nk}(\mathbf{x}, t; \mathbf{x}', t') = u_n(\mathbf{x}, t) \quad (2)$$

where $u_n(\mathbf{x}, t)$ satisfies the Navier equation:

$$\rho \frac{\partial^2}{\partial t^2} u_n(\mathbf{x}, t) = (\lambda + 2\mu) \nabla(\nabla \cdot u_n(\mathbf{x}, t)) + \mu \nabla^2 u_n(\mathbf{x}, t) + F(\mathbf{x}, t) \quad (3)$$

The assumption of a homogeneous isotropic elastic medium implies the P and S waves velocities in the medium are uniform:

$$v_p = \sqrt{\frac{\lambda + 2\mu}{\rho}} \quad (4)$$

$$v_s = \sqrt{\frac{\mu}{\rho}} \quad (5)$$

In general, P and S wave velocities are not constant throughout a true elastic medium, in which case the Green's function $G_{nk}(\mathbf{x}, t; \mathbf{x}', t')$ is not determined by an analytic solution to Eq. (3). Therefore we prefer direct measurement on full-scale devices, with 3D sensors.

In terms of the transfer function, Green's function is the spatial and temporal impulse response of the system defined by the wave equation. This is the signal that a perfect sensor would register, in any propagation medium, if the source were a pulse $\delta(\mathbf{x} - \mathbf{x}')\delta(t - t')$.

By definition, δ contains all frequencies. G_{nk} has the particularity of containing all the information related to propagation. If we know G_{nk} , we can know the structure of the medium. Whether earthquake, explosion or vibrating truck, dynamic compaction, the signal recorded by the receivers always contains the signature of the source. It then becomes difficult to determine which part of the signal corresponds respectively to the source and to the medium. Only precise knowledge of the source (frequency band, amplitude) can allow one, by a convolution operation, to go back to G_{nk} . In natural medium, this knowledge is always limited and G_{nk} can only be approximated.

For the case of structured soils with vertical elements (holes, inclusions), we build another type of anisotropic medium. We hope the natural soil is as thick and homogeneous as possible. Through measurement, we obtain experimental Green's functions in an anisotropic medium, approximate because the real impact is not a Dirac function, but a Ricker-like function (Fig. 8) in time series. It is noted here that the dynamic compaction, on compressible granular soils, causes a signal focused around 9.5 Hz. About two thirds of the energy emitted on impact propagate as Rayleigh waves.

Extracting information

Several ways of valuing complex signals measured on the surface have been developed (Brûlé, 2023). We retain the approaches in total energies integrating all the time steps over the duration of the recording and energy snapshots for each time step. The transfer functions, ideal for studying frequency effects, obtained for two configurations are also used. First, the functions calculated between

Fig. 8 Signal measured along x by a sensor located at 10 m from the point of impact on the ground of the 17 t compaction mass (red solid line) and in dotted blue line, the theoretical function representing a Ricker function of order 2.

Fig. 9 (a) Top schematic view of the full-scale experiment of Saint-Priest (2012), see also photos in Fig. 2. Purple disks are cylindrical vertical holes (5 m in depth) and black square is the sensor located at the surface. Red disk is the impact point source. Blue solid lines are accelerograms in time series (x component). (b) The graph represents the inverse of the Green's function according to x for the sensor F_1 located in the grid of holes.

two points located at the same place, before and after inclusions in the ground, then the functions calculated between two distant points, also before and after inclusions. As mentioned previously, we also have the case of approximate and experimental Green functions for the case of impact sources. Thus Fig. 9a shows the signal along x -axis recorded at 5 m from the source (and assimilated to the source) and the signal along x -axis recorded in the network of holes (sensor F_1). One can notice the rapid energy decrease over a short distance (25 m). In Fig. 9b, we can see the experimental Green's function along x -axis (Boué and Paul, 2020). To better highlight the frequency content of this function, we have chosen to represent its inverse $1/G_x$. We see that this function reflects de-amplification at low frequency below 2 Hz and between 7 and 10 Hz.

$$\frac{v_x(\omega)}{s_x(\omega)} = G_x(\omega) \quad (6)$$

Between the hollow cylinders, the energy can be channeled too (Brûlé and Guenneau, 2021).

Conclusion

This chapter on seismic metamaterials highlights the reality of the interaction of buried structures with short seismic wavelengths (tens to hundreds of meters). We have shown that it is possible in principle to achieve a significant control of seismic waves (intensity and frequency content) in artificially structured soils. Seismic metamaterials could be complementary to the existing passive systems used in earthquake engineering. Finally, we note that seismic metamaterials can be classified as in Fig. 7, and notably some of them can be found in nature as forest of trees (Colombi et al., 2016). It is actually possible to show a complete correspondence for Love waves propagating in forests of trees and spoof plasmon polaritons propagating at structured metal surfaces (Maurel et al., 2018). We believe that seismic metamaterials based on analogies with photonic crystals might offer some interesting perspectives in earthquake protection and energy harvesting (Guenneau et al., 2018; Brûlé and Guenneau, 2021).

However, there is more to seismic metamaterials. These are based on analogies with electromagnetic metamaterials which is a research area at the interface between different disciplines. Electromagnetic metamaterials encompass notably the field of transformation optics that got started with the seminal paper (Pendry et al., 2006). Transformation optics essentially develops a theory of graded metamaterials that are anisotropic, based on Maxwell's equations that behave nicely under geometric transforms. Indeed, starting from a reference medium that is isotropic and homogeneous (typically vacuum in optics, what amounts to a homogeneous soil in geophysics), it is possible to locally distort the virtual electromagnetic space to detour wave trajectories at will: as an illustrative example, space geodesics that are straight lines in flat space, are curved lines in a non-Euclidean space such as the surface of the sphere, and everyone has experienced that shortest trajectories are no longer straight lines when traveling long distances on airplanes. However, one does not need to resort to non-Euclidean spaces to distort geodesics: it is enough for that to make a coordinate change in a flat space that maps a disk onto a ring to create a hole in the flat space (literally by blowing up a point). This bold proposal of Pendry and coworkers was first met with gentle skepticism in 2006, but this exclusion zone created by the invisibility cloak was rapidly validated experimentally for microwaves at 8.5 GHz in a follow up article of (Pendry et al., 2006). Using the similar formalism, it is possible to design some invisibility cloaks for different types of waves, even for governing equations which are not transformation invariant, such as the elasticity equations. In Xu et al. (2015), a metamaterial cloak 20 cm in diameter designed at the Institut Fresnel in 2006 to control linear surface water waves (Farhat et al., 2008), is shown to also work for

Fig. 10 Concept of invisibility cloak for surface (Rayleigh) seismic waves: (a) Point force in a thin homogeneous isotropic elastic plate generating a concentric flexural wave; (b) Same as (a) when the point force is located in the neighborhood of an invisibility cloak (consisting of a spatially varying anisotropic medium) that hides a clamped F-shaped obstacle; (c) Same as (b) when the cloak is removed; (d) Photo of a multi-physics Fresnel cloak designed for acoustic waves, water waves and electromagnetic waves (Farhat et al., 2008; Xu et al., 2015), see also Fig. 6c for its seismic counterpart; (e) Experimental demonstration of microwave cloaking (credit: Redha Abdeddaim and Elodie Georget, Institut Fresnel); (f) CNRS infographic for a seismic cloak based upon (a–e).

airborne acoustic waves and microwaves (in one light polarization) in the same range of wavelengths: indeed, in a cylindrical configuration the same Helmholtz equation can be used for all three types of waves, and the transformed medium parameters are achieved using some homogenization approach based on perforated media, that is simply underpinned by geometrical considerations. The three types of perforated media correspond in Xu et al. (2015) to the metamaterial shown in Fig. 10d, that is either perforating a free air-liquid interface (for surface water waves), or perforating air (in the sense that the pillars constituting the metamaterial are rigid inclusions for airborne acoustic waves and infinite conducting inclusions for the transverse magnetic polarization at GHz frequencies). Mathematically, one supplies the Helmholtz equation with Neumann boundary conditions on the perforations. Clearly, the cloak works as expected in Fig. 10e, since the wavefield is almost unperturbed outside of the cloak and is vanishing inside the exclusion zone. This is achieved through the required artificial anisotropy of the effective medium within the ring that finely approximates the transformed medium parameters. This experimental validation for broadband cloaking for microwaves (between 3 and 7 GHz) confirmed similar experiments for water waves (between 8 and 15 Hz (Farhat et al., 2008)) and for airborne sound waves (between 4 and 8 kHz) by the group of Nicholas Fang at Massachusetts Institute of Technology in 2013. The same geometry allows for the control of flexural waves in thin elastic plates as theoretically and numerically shown in Mohamed et al. (2009) and experimentally demonstrated in Stenger et al. (2012). We propose to scale up the Fresnel cloak to design a seismic cloak for surface Rayleigh waves that would consist of same arrangement of concrete pillars buried in soil, as depicted in Fig. 10f. Transformation elasticity and homogenization theory predict similar effect of wave control. Fig. 10 summarizes our strategy for the design of such a seismic cloak based on analogies with optics.

We hope we have convinced the reader of this Chapter that the field of seismic metamaterials is worth investigating and we hope that new proposals will emerge from cross-disciplinary collaborations in condensed matter theory, wave physics and civil engineering.

Abstract

Reduced size in one, two or three (all) dimensions leads to quantum effects when the length scale comes into the range of the de Broglie matter wavelength. Among these effects are size quantization and the associated sublevels and changes in the density of states, tunneling and interference effects, single electron effects, as well as coherence and entanglement.

Key points

- Quantum mechanical confinement in 1, 2 and 3 dimensions.
- The effects of tunneling, coherence and entanglement.
- Connecting physical effects and device functionality.
- Improving device performance and new device principles.

Introduction

A “quantum device” could be defined as a device whose functionality or principle of operation depends essentially on quantum mechanical effects. However, this definition somehow seems too vague. For example, a chair obtains its holding power from the quantum mechanical overlap of the wave functions of its constituents or a toaster relies on quantum mechanical scattering processes for converting electrical current and power into heat. Therefore a “quantum device” shall be defined here more rigorously as a “device that intentionally employs or harnesses quantum mechanical effects for its operation.” This article is limited to condensed matter devices, thus completely (but intentionally) bypassing the “natural” use of quantum mechanics in living organisms.

A large number of devices already function based on the control of quantum mechanical interactions or effects. Prominent examples are the LASER (light amplification by stimulated emission of radiation) and the SQUID (superconducting quantum interference device). A possibly larger number awaits its commercialization or even their invention. This section discusses, in particular, quantum devices with “reduced dimensionality.” These shall be understood as devices that rely on structures that confine charge carriers in one, two, or all three dimensions. Such systems are called quantum films or wells, quantum wires, and quantum boxes or dots, respectively. Given the typical de Broglie wavelength of electrons in semiconductors, typical sizes of such structures are in the 1–10 nm range. It is noted that currently (2022) the smallest feature size in mass-market consumer electronics is below 10 nm. Over the years, the predicted miniaturization limits have hit many marks which have been overcome by ingenuity. Clearly though the granularity of matter limits the miniaturization of individual devices at the atomic level or the lattice constant of solids (about 0.5 nm). Therefore, quantum and statistical effects seem unavoidable even in mainstream microelectronics.

The natural enemies of quantum devices are dephasing events such as scattering of an otherwise coherently evolving quantum state, increasing temperature, either due to higher scattering rate or the modification of thermodynamic distribution functions, and increasing structural size, mostly leading to a transition to classical behavior.

[☆]Change History: September 2022. M Grundmann updated Tables 1 and 2.

Quantum mechanical effects

The quantum effects that are used in quantum devices are sorted by increasing order of complexity and decreasing order of fundamental understanding and employment in devices:

1. single particle effects,
2. Pauli's exclusion principle,
3. quantization of electronic states in confining potentials,
4. tunneling effect,
5. spatial and temporal coherence of the wave function,
6. spin,
7. quantum liquids, and
8. entanglement.

Examples for the use of these effects in condensed matter devices is discussed below. The list, however, may not be exhaustive as eventually any quantum mechanical effect, for example, the quantization of other degrees of freedom or still unexplored effects, may be used in devices.

Quantization in potential wells

Quantum devices of reduced dimensionality depend some way or another on the presence of potential wells that limit the motion of charge carriers in c dimensions compared to bulk material. The motion can be limited in one dimension within a quantum film or well (QW), in two dimensions within a quantum wire (QWR), or in all three dimensions within a quantum dot (QD) or box. These structures can be combined to double or multiple structures or even periodic arrays (Table 1).

The confining potential can arise from applied spatially modulated electric potentials or the effect of band offsets in heterostructures or a combination of both. The quantization depends on the size, shape, and barrier height of the confining potential. By controlling the barrier height between confinement structures the degree of quantum mechanical coupling can be varied.

The simplest picture arises from the particle in a rectangular box with side lengths L_x , L_y , and L_z and infinite barriers. The quantization energy is given by

$$E = \frac{\pi^2 \hbar^2}{2m} \left(\frac{n_x^2}{L_x^2} + \frac{n_y^2}{L_y^2} + \frac{n_z^2}{L_z^2} \right)$$

with m being the effective mass of the particle (here taken as isotropic) and the n_i being the quantum numbers ($n_i \geq 1$).

If the confining potential is harmonic, the energy levels are equidistant.

$$E = (d/2 + n)\hbar\omega$$

$d = 3 - n$ shall be the dimension of the confinement potential with n being the number of unconfined dimensions (see Table 1). For a parabolic confinement potential, the generalized Kohn's theorem applies, which states that the resonance energies of many electrons in the dot are the same as for a single electron and that dipole radiation interacts only with the center of mass motion of the electrons.

Since self-assembled nanostructures often involve strained systems, the confining potential depends on the local strain and the resulting piezoelectric field which both may be spatially strongly inhomogeneous.

The finite barrier height limits the number and the localization energy of confined states. In quantum dots, there is a critical minimum size for which at least one state is confined. Quantum dots smaller than the critical size do not exhibit any confined states, as opposed to quantum wells that always exhibit at least one localized and quantized state.

Two-dimensional carrier gases

A particularly important confined electron system is the two-dimensional electron gas (2DEG). Such a gas can develop in a quantum well. However, a single interface between two semiconductors of different bandgaps is sufficient to cause the creation of a 2DEG. If modulation doping, that is spatially inhomogeneous doping, is used, a high carrier concentration can be achieved in the 2DEG without the dopant atoms being located in or close to the 2DEG. In this way, impurity scattering is avoided and a high

Table 1 Structures with two-, one-, and zero-dimensional confinement.

Confinement of motion to n dimensions	Name	Combination of two	Periodic structure
2	Quantum well	Double quantum well	Superlattice
1	Quantum wire	Quantum wire pair	Quantum wire array
0	Quantum dot	Quantum dot molecule	Quantum dot chain/array

mobility is achieved. For GaAs/AlGaAs structures the mobility record (2004) stands at $3.1 \times 10^7 \text{ Vs cm}^{-2}$ low temperatures. Thus, 2DEG and its manipulation are the basis for many quantum devices, in particular exhibiting magneto-transport effects. In a high electron mobility transistor (HEMT), the transport in a 2DEG is used as channel conductivity in a field effect transistor. HEMTs display high transconductance and low noise figure and are used for many high-frequency applications such as satellite receivers. In order to maximize the carrier confinement, pseudomorphic quantum wells, for example, InGaAs/AlGaAs on GaAs, are used. The highest performance is achieved with InGaAs/InAlAs quantum wells on InP substrate. In order to transfer this technology to (larger and cheaper) GaAs substrates, a metamorphic, dislocated buffer is grown, and such a device is called MHEMT. Similar strategies apply to SiGe/Si HEMTs.

Magnetotransport effects in 2DEGs at low temperature have been studied in detail. In the integral quantum Hall effect (IQHE) the conductivity of the 2DEG exhibits extended plateaus for a range of magnetic fields with a well-defined conductivity value σ_{xy} that takes integer multiples of $e^2 h^{-1}$, the (inverse) von-Klitzing constant (von Klitzing et al., 1980). This quantum mechanical value is found to be independent from details of the sample (within reasonable spread) such as doping, layer thickness, and growth method. The IQHE can be used for fabrication of a standard for the resistance and the unit “Ohm” (Bachmair et al., 2003). The precision of the QHE normal is two orders of magnitude better than the realization of the ohm in the old SI system. For this purpose, parallel and serial circuits of QHE resistors can also be used and an AC measurement technique can be devised.

It is to be noted that more complicated phenomena, the fractional quantum Hall effect, are observed and discovered in such quantum liquids at even more extreme conditions (very low temperatures and high magnetic fields).

Quantum wells are also very successfully used as active mediums in semiconductor laser diodes. Charge carriers are captured efficiently from the barrier material (high bandgap) into a quantum well or multiple quantum wells (low bandgap). Due to their small thickness, a high-density carrier gas is easily achieved and inversion is reached quickly. The finite density of states at the sub-band edges provides a favorable gain spectrum. This leads ultimately to low lasing threshold current density of $\sim 40 \text{ A cm}^{-2}$ (Grundmann, 1999). Their combination with high-finesse optical cavities using high-reflectivity dielectric layer packages (Bragg mirrors) leads to vertical surface emitting lasers (VCSEL) and tests the use of quantum electrodynamic (QED) effects (e.g., the modification of spontaneous emission lifetime—Purcell effect).

Quantum wires

Many device applications have been envisioned for quantum wires. Since they are positioned in terms of reduced dimensionality between quantum wells and quantum dots, for some properties the ultimate solution is quantum dots. Since quantum dots can be fabricated in a self-assembled manner, they have made some of the quantum wire devices and approaches obsolete.

However, quasi-one-dimensional conduction poses interesting physics (e.g., reduced scattering and Luttinger liquids). Quantum wires can be used also as channels in transistors. In order to draw a sufficient current, many wires may have to be used in parallel. Due to the one-dimensional k -space, carrier scattering is reduced and thus a higher mobility should be possible. Recent progress in the self-assembled fabrication of quantum wire nanowhiskers or nanorods/nanopillars and heterostructures incorporated in them makes them seem attractive for a variety of applications including LEDs, lasers, and sensors.

Quantum dots

Quantum dots confine carriers in all three spatial dimensions. These are therefore sometimes termed “artificial atoms.” The embedding into a solid-state matrix makes them more readily accessible to manipulation with electrodes, currents, fields, etc. than atoms in a trap. However, this comes at the price of stronger (compared to ions in a trap) coupling to external degrees of freedom, such as charge fluctuations and thermal bath.

The primary effect of quantum confinement is to create singular density of states at the quantized levels. The energetic broadening for a single quantum dot is typically small at low temperature (μeV range). With increasing temperature, additional dephasing mechanisms can increase the homogeneous broadening to the 10 meV range. An ensemble of quantum dots exhibits inhomogeneous broadening because the individual nanostructures are not exactly identical with respect to size, shape, and possibly chemical composition. The ultimate type of quantum dot is a single lattice defect, often termed “color center,” NV (nitrogen-vacancy) centers in diamond being a prominent example. Devices based on single dots have been envisioned, realized, and investigated for storage of single electrons, emission of single or entangled photons, and quantum information processing.

The storage of single electrons is comparably straightforward. The capture of a single electron causes a second electron to need a larger energy to be on the dot due to Coulomb repulsion. While for typical shallow donors in semiconductors this effect is so strong that only the neutral state (with one electron) is localized, the Coulomb interaction energy in self-assembled quantum dots is typically in the range of 20 meV. At sufficiently low temperature for a given potential landscape, a second electron cannot enter the dot (Coulomb blockade) and the dot charge is fixed to an integer number of electrons, possibly one or zero. The storage of single electrons has been successfully demonstrated at low temperatures. Efforts are underway to maintain the effects up to liquid nitrogen temperature. The dots are typically built into a transistor structure to make a single electron transistor (SET). Here the gate electrode contains the quantum dot close to the channel. Due to electrostatic interaction the source-drain channel only becomes conductive after a sufficient source-drain voltage larger than the voltage related to the Coulomb energy has been applied. Conversely, in a single-electron memory, the conductance of the SET can be used to test whether a single electron is located on the quantum dot or not. By periodically modulating the applied bias voltages in a suitable manner with a frequency f ,

a single electron can be transferred by tunneling onto and off the dot from source to drain for each cycle. Such a device is called turnstile device and can be used to define a current normal via $I = f e$.

Quantum dots can be used in what is called a "photon gun." In such a device, a trigger impulse causes the reliable emission of a single photon. This is a nonclassical form of light which cannot be produced from dimming a conventional source. In classical light the time difference between photons follows Poisson statistics while a photon gun is supposed to create a periodic stream of single photons. With such photons, higher data rates for quantum cryptographic transmissions can be realized. Upon trigger the pulse carriers are injected into the quantum dot. Emission on the single exciton line occurs only once for each trigger with little time delay between trigger and emission.

The emission of entangled photons is possible if the cascade relaxation from biexciton to exciton and exciton to empty quantum dot is used. If the single exciton state is degenerate with respect to the two in-plane polarization directions, the photons are entangled and can be used for quantum cryptographic information transmission schemes. The polarization degeneracy calls for quantum dots with certain geometrical symmetry as strain, piezoelectric fields, and geometric asymmetries contribute to the lifting of the degeneracy. The two emitted photons have different energies unless the biexciton binding energy is zero. This is generally possible and depends on the size and shape of the quantum dot.

Several schemes have been devised to use quantum dots in quantum computing schemes. The spin degree of freedom seems a good candidate for quantum computational operations due to its long dephasing time of up to several milliseconds. Many of the current experiments involve optical sampling of the quantum information with polarized light and suitable pulses. NV centers are an example of quantum dots for which the spin state can be coherently manipulated even at room temperature. Electronic means are easier to integrate for access the quantum dots, making electrical readout of quantum information an active field. This has been accomplished for NV centers but also for quantum dots defined with in-plane gates, but for the latter only at very low temperatures. Using clever combinations of the Coulomb blockade mechanisms and external bias, the occupation and the spin orientation of a single electron can be tested electronically at low temperatures. Quantum computing schemes based on cellular automata (QCA) have been proposed extensively to realize quantum computational algorithms. QCA rely on arrays of quantum dots that interact to allow for switching of their polarization state.

Quantum dots can be used as active-gain medium in semiconductor diode lasers, which record small transparency current densities due to the fairly small volume for carrier inversion. Till date, reasonable laser performance has been obtained by using only self-assembled quantum dots. The discrete density of states leads, in an ideal situation, to very large T_0 values (small temperature-dependence of the threshold current) and zero α -factor (also termed line width enhancement factor). Realistically, the T_0 values have been found to be large (close to infinity) only up to 150–200 K; for higher temperatures the T_0 values are not particularly advantageous compared to conventional quantum well lasers because of loss of carriers from the quantum dots due to thermal excitations or the Auger effect. Small α -factors have been realized, also leading to a reduction of current filamentation and a homogeneous optical near field. These properties allow for improved high-power lasers.

Typically, lasing is designed to occur on the ground state of the quantum dots since this results in the lowest threshold (below 10 A cm^{-2}) for laser diodes. Excited states provide higher gain and can be made to contribute to the lasing process simultaneously with the ground state. By intentionally increasing the width of the inhomogeneous broadening, for example, by growing vertically stacked dots with slightly different geometrical properties, the gain spectrum can be made very broad. Such gain medium would allow for wide tunability.

The management of strain and chemical composition allows to create 1300 and 1550 nm emission, important for datacom and telecom applications, respectively, on GaAs substrate. In particular, the use of metamorphic buffers has been successful recently. Quantum dot lasers are found to have a strongly improved radiation hardness compared to quantum well lasers.

Josephson junctions

A Josephson junction is made up from two superconductors sandwiching a thin non-superconducting layer such that electrons can tunnel through the barrier. The coherence of the wave function in the superconductor leads to DC or AC currents. The DC Josephson current is proportional to the phase difference between the two superconductors. The frequency f of the AC Josephson current is proportional to the voltage V applied across the junction, $f = 2eV/h$. This allows for a voltage normal based on a frequency. A Josephson junction standard can realize a voltage with an accuracy of 10^{-10} . For a standard in the volt regime several thousand junctions are put in series. A superconducting loop with two Josephson junctions in either arm is very sensitive (10^{-14} T) to the magnetic flux enclosed (SQUID, superconducting quantum interference device).

Conclusion

Devices relying on quantum effects have a broad spectrum of applications (Table 2). Generally, it is difficult to achieve operation at ambient temperatures. Great progress has been made in the field of metrology where quantum devices will become standards that can be easily reproduced, at least in a laboratory environment. Room temperature operation has been achieved, for example, for quantum dot lasers with the preservation of several advantages from the quantum nature of the gain medium.

Table 2 Quantum devices, the effects they are based on, and applications.

<i>Device</i>	<i>Quantum effect</i>	<i>Performance/Use</i>
High electron mobility transistor	2D confinement	High-speed, low-noise amplifier, low-threshold laser
Quantum well laser	2D confinement	Low threshold
Quantum dot laser	0D confinement	Low threshold, small α
Quantum Hall effect	Quantum liquid	Resistance standard
Electron turnstile	Tunneling, single electrons	Current standard
Photon gun	Single-particle effect	Quantum cryptography
Quantum cellular automata	0D confinement, coherence	Quantum computing
Quantum dot, color centers	Entanglement, coherence	Quantum computing, quantum cryptography, quantum sensing
Josephson junction	Coherence of wave function	Voltage standard
SQUID	Coherence of wave function	Sensitive magnetometer

Abstract

Thermocouples have long been used for the measurement of temperature, but they can also be used as heat engines for the generation of electrical power and for heat pumping or refrigeration. However, their efficiency as generators and their coefficient of performance as heat pumps fall well short of the ideal limits. This is because the reversible thermoelectric effects are always accompanied by the irreversible phenomena of electrical resistance and thermal conduction. It is shown that the performance of thermoelectric energy converters can be expressed in terms of a quantity known as the figure of merit. The figure of merit is highest for semiconductors that have a low lattice thermal conductivity, a high carrier mobility and a high density of electronic states. The figure of merit is high in both p-type and n-type bismuth telluride, though there is still plenty of room for improvement. It is explained that the electronic parameters can be optimized for a given thermoelectric material. Also, various means of reducing the phonon conductivity are discussed. These include the use of solid solutions rather than simple elements and compounds and the reduction of the grain size to enhance boundary scattering. Mention is made of PGEC materials that combine phonon transport in glass with electron transport in crystals. There is also the possibility of improving the figure of merit by making use of nanostructures. However, it is also argued that the performance of thermoelectric energy converters is unlikely to exceed about 40% of that of an ideal thermodynamic machine.

Introduction

The discovery of thermoelectricity is usually attributed to Thomas Seebeck and Jean Peltier and the two main effects are named after them. When the junction between two different electrical conductors is heated, an electromotive force is developed. This is the Seebeck effect. Similarly, when an electric current is passed through such a junction, Peltier heating or cooling is observed. Despite the thermoelectric effects appearing at the interface between two conductors, the Seebeck and Peltier coefficients are essentially bulk properties. Absolute values for these coefficients in a given material can, in principle, be defined by supposing that it is joined to a superconductor, all superconductors having zero Peltier and Seebeck coefficients.

It was shown by Kelvin that the Seebeck coefficient, α , is related to the Peltier coefficient, π , by the expression $\pi = \alpha T$. This is of practical significance since the Seebeck coefficient is much easier to measure than the Peltier coefficient. Thus, even when a thermocouple is used as a heat pump or refrigerator, its performance can be expressed in terms of the Seebeck coefficient.

When there is both a flow of current and a temperature gradient in a single material, a third thermoelectric effect is apparent. This reversible heating or cooling is related to the Seebeck and Peltier effects and is known as the Thomson effect. It can be used in the extrapolation of the Seebeck and Peltier coefficients to elevated temperatures.

The thermoelectric effects can be exploited in the generation of electricity from heat and in heat pumping or refrigeration. The effects are reversible, but they are always accompanied by the irreversible effects of electrical resistance and heat conduction. This means that the efficiency of a thermoelectric generator is usually much smaller than that of an ideal heat engine. Likewise, the coefficient of performance (COP) of a thermoelectric heat pump is limited by the irreversible effects. The need for materials with large thermoelectric coefficients and small electrical resistivity and thermal conductivity has long been realized (Altenkirch, 1911), but suitable thermocouples did not become available until the 1950s.

A thermoelectric energy convertor usually consists of a number of thermocouples connected thermally in parallel and electrically in series. Each thermocouple has a positive and negative branch. The dimensions of the branches are selected so as to minimize the combined effects of electrical resistance and heat conduction.

Let us suppose that the temperature difference between the hot and cold junctions is small compared with the absolute temperature; $\Delta T/T \ll 1$. Then the efficiency, η , is given by

$$\eta \simeq \frac{\Delta T}{T} \left(\frac{M-1}{M+1} \right) \quad (1)$$

and the coefficient of performance, ϕ , is given by

$$\phi = \frac{T}{\Delta T} \left(\frac{M-1}{M+1} \right) \quad (2)$$

In these equations the quantity M is equal to $(1 + ZT)^{1/2}$ where Z is known as the thermoelectric figure of merit (Ioffe et al., 1957).

The thermoelectric figure of merit

The figure of merit of a thermocouple is given by the expression

$$Z = \frac{(\alpha_p - \alpha_n)^2}{\left\{ (\lambda_p \rho_p)^{1/2} + (\lambda_n \rho_n)^{1/2} \right\}^2} \quad (3)$$

where λ represents the thermal conductivity and ρ represents the electrical resistivity. The subscripts p and n indicate the positive and negative branches respectively. It is assumed that the relative dimensions of the branches have been optimized.

It is common practice to make use of a figure of merit for a single material, that is either the positive or negative branch. This quantity is equal to $\alpha^2/\lambda\rho$ and will be denoted by the symbol z . Usually the thermocouple figure of merit, Z , is close to the average of the figures of merit z_p and z_n for the two branches. More often than not, one encounters the dimensionless figure of merit, ZT , rather than Z , and recently, a method that uses Peltier cooling was developed for measuring the dimensionless figure-of-merit of a semiconductor using semiconductor-metal thermocouples (Bhattacharya et al., 2022).

The product $\lambda\rho$ has its smallest value for metallic conductors but unfortunately the Seebeck coefficient is then also small. Much larger Seebeck coefficients are to be found for semiconductors but then the product $\lambda\rho$ also becomes larger. This is because the conduction of heat by the lattice vibrations is dominant in such materials. In general, one can optimize the figure of merit for a semiconductor by changing the carrier concentration using donor or acceptor impurities.

The effect of changing the carrier concentration can be described in terms of the position of the Fermi level within the energy bands. The Fermi level is the energy at which the probability of a state being occupied is $1/2$. The thermoelectric coefficients depend on the energy difference between the Fermi level and the edge of the appropriate band. The valence band contains the so-called positive holes while the conduction band contains the negative carriers, the electrons. It is preferable for the energy gap between the conduction and valence bands to be large enough for only one type of carrier to contribute significantly to the transport processes. When both types of carriers are present they act in opposition to one another. For a p-type or positive thermoelectric material the Fermi level lies in or near the valence band and for an n-type or negative material it lies close to the conduction band.

The contribution of the carriers in a particular band depends on their concentration and on their mean free path. Both these quantities in turn are related to the effective mass of the carriers. A large effective mass is beneficial in that it implies a large density-of-states, but it also means that the scattering of the carriers is stronger. Actually, there is more than one effective mass. Thus, there is a density-of-states mass and an inertial mass. The two are related to one another but it is possible to find a low inertial mass combined with a high density-of-states mass in a multi-valley semiconductor. In such a material the band edge is located, not at the center of wave-vector space, but at multiple points that satisfy the crystal symmetry.

A good thermoelectric material combines a high density-of-states mass, m^* , with a high mobility, μ . It is also necessary for the lattice thermal conductivity, λ_L , to be as small as possible. In the search for thermoelectric materials, we look for a high value of $(\mu/\lambda_L)(m^*/m)^{3/2}$ where m is the mass of a free electron. It is common practice (Chasmar and Stratton, 1959) to combine these properties in a parameter β that is defined by the equation

$$\beta = \left(\frac{k}{e}\right)^2 \frac{\sigma_0 T}{\lambda_L} \quad (4)$$

where

$$\sigma_0 = 2e\mu \left(\frac{2\pi m^* kT}{h^2}\right)^{3/2}. \quad (5)$$

Of course, besides selecting a material with a high value of β it is also necessary to optimize the carrier concentration.

Optimizing the Seebeck coefficient

Let us discuss the effect of changing the Fermi energy when there is only one type of carrier, say positive holes. The Seebeck coefficient will become larger as the Fermi level moves away from the valence band edge into the energy gap. On the other hand, this will lead to a decrease in the carrier concentration. To obtain a high figure of merit it is desirable that the quantity α^2/ρ , known as the power factor, should be large. This usually means that the Fermi level should lie close to the band edge and the Seebeck coefficient is then of the order of $\pm 200 \mu\text{V/K}$. However, we must also take into account the effect of the electronic thermal conductivity, which will generally not be negligible compared with the lattice contribution. This means that the optimum Seebeck coefficient will be greater than that which yields the highest power factor.

In Fig. 1 we show the variation of zT with Seebeck coefficient for materials with different values of $(zT)_{\max}$ (Goldsmid, 2017). In fact, values of $(zT)_{\max}$ for the best present-day thermoelectric materials do not exceed 3 so the optimum Seebeck coefficient is never more than about $\pm 300 \mu\text{V/K}$.

Semiconductor thermoelements

The Seebeck effect has long been used for the measurement of temperature. For that purpose, at least one of the branches of the thermocouple is a metal or metallic alloy. However, by the middle of the twentieth century it was realised that worthwhile figures of merit could only be achieved using semiconductors. The question, then, was how to find a semiconductor with a large value of β .

A major contribution was made by Ioffe and Ioffe (Ioffe and Ioffe, 1954) who carried out a systematic study of the lattice thermal conductivity of non-metallic crystals. They showed that in any given series of elements or compounds the lattice conductivity fell with increasing mean atomic weight. This idea is exemplified by the compound PbTe which was one of the first materials to be used

Fig. 1 Plots of zT against Seebeck coefficient for various values of $(zT)_{\max}$. The graphs are for n-type material but would be identical for p-type material apart from the sign of the Seebeck coefficient. Reproduced with permission from Ref. Goldsmid HJ (2017) *The Physics of Thermoelectric Energy Generation*. IOP Publishing: Bristol.

in practical thermoelectric generators. Likewise, the compound Bi_2Te_3 was the first material to be used in thermoelectric refrigerators that could yield worthwhile depressions of temperature through the Peltier effect (Goldsmid and Douglas, 1954). A simple theory relating the lattice conductivity to the mean atomic weight has been developed by Keyes (Keyes, 1959).

Since its introduction in the mid-1990s bismuth telluride and its alloys have remained the most widely used thermoelectric materials. Bismuth telluride in both its p-type and n-type forms has a value for the product $\mu(m^*/m)^{3/2}$ that is higher than for almost any other semiconductor. Not surprisingly, in view of its high mean atomic weight, the lattice thermal conductivity is also exceptionally low. There are, however, some features of bismuth telluride that are unfavorable. The energy gap is no more than 0.13 eV which means that it is difficult to avoid the influence of minority carriers. This problem becomes more severe as the temperature is raised so bismuth telluride becomes unsuitable for generation and refrigeration at elevated temperatures. Also, the structure is such that the compound forms crystals that are weakly bonded in the trigonal direction, a factor that must be borne in mind when designing thermoelectric modules.

The figure of merit of both p-type and n-type bismuth telluride is highest for current flow perpendicular to the trigonal axis, that is parallel to the basal planes. It is not necessary that the material be in the form of a single crystal. Polycrystalline sintered material is mechanically stronger than single crystals and can be preferentially aligned if produced by extrusion or hot pressing (Airapetyants and Efimova, 1958).

Reducing the lattice conductivity

Ioffe and his colleagues (Ioffe et al., 1956) showed that the figure of merit of any particular element or compound can be improved by forming a solid solution or alloy. Thus, the lattice conductivity of bismuth telluride can be reduced by forming a solid solution with antimony telluride or bismuth selenide. Likewise, lead telluride can be improved by alloying with lead selenide. Perhaps surprisingly, the formation of a solid solution does not necessarily affect the mobility of the charge carriers provided that the long-range order is maintained.

Of particular interest are the alloys of silicon and germanium. Silicon is one of the few semiconductors that has a product $\mu(m^*/m)^{3/2}$ that is substantially superior to that of bismuth telluride. However, the lattice conductivity of silicon is exceptionally high, being comparable with the total thermal conductivity of most metals. The value of β for silicon is, therefore, not very large but this quantity becomes more promising for silicon-germanium alloys and, in fact, these are worthwhile generator materials.

It is well known that the lattice conductivity of a crystal can be reduced by making the grain size smaller but this is usually thought of as a low-temperature phenomenon (Blakemore, 1985). However, boundary scattering can also be observed at high temperatures. It is likely to be most noticeable for solid solutions in which most of the heat is carried by low-frequency phonons. Boundary scattering has been observed at ordinary temperatures for silicon-germanium alloys.

The lattice conductivity of bismuth telluride is of the order of 1 W/m K and similar values are found for some other crystalline materials but substantially lower values are expected for glasses. Slack introduced the useful concept of a PGEC that is a phonon-glass electron-crystal. It has been shown that promising thermoelectric properties can be found among crystals that have large unit cells containing loosely bound atoms.

Thermoelectric materials

In spite of the fact that bismuth telluride and its alloys have been in use as thermoelectric materials for more than half a century, they are still the basis of most thermoelectric refrigerators. They have also been used in generators at moderately high temperatures, but their small energy gap is a severe disadvantage for most generator applications. There are, however, several other materials that have attracted interest in the field of thermoelectric energy conversion.

One of the earliest materials to be studied was the semi-metal, bismuth. Although it has a negative energy gap (that is an overlap of the conduction and valence bands) the transport properties are dominated by the electrons, and it was used as a negative thermoelement with bismuth telluride as the positive branch in the earliest thermoelectric refrigerator.

It has been found that certain alloys of bismuth and antimony have a positive energy gap, and are marginally superior to bismuth telluride at low temperatures (Yim and Amith, 1972). The electrons in bismuth and Bi—Sb alloys have a high mobility and, therefore, exhibit large magneto- thermoelectric effects (Horst and Williams, 1980). These include not only longitudinal changes in the thermoelectric parameters but also transverse effects. The transverse equivalents of the Seebeck and Peltier effects are the Nernst and Ettingshausen effects. They have an advantage over the longitudinal effects in that they allow independent control of the electrical and thermal resistance in perpendicular directions.

Compounds and alloys based on lead telluride have a larger energy gap than bismuth telluride, 0.3 eV compared with 0.13 eV, and have long been used in thermoelectric generators. The so-called TAGS materials are alloys of AgSbTe_2 with GeTe . They are closely related to PbTe although they do not have the rock salt structure. They have values for $z_p T$ in excess of unity at temperatures greater than about 600 K (Skrabek and Trimmer, 1994). A related compound that exhibits the largest value of zT at present is SnSe . At ordinary temperatures it has a distorted rock salt structure that changes to the undistorted form above 800 K. SnSe is remarkable in that zT is as high as 2.62 at 923 K (Zhao et al., 2014). The main reason for this exceptional value is a lattice conductivity of only 0.23 W/m K.

Silicon-germanium alloys have already been mentioned and have come into their own at high temperatures. In fact, one might have expected them to be even better since electrons in *pure* silicon have a value for $\mu(m^*/m)^{3/2}$ about four times greater than in bismuth telluride. However, for thermoelectric applications one needs to add donor impurities to such a level that ionized-impurity scattering has substantially reduced the mobility. It has been suggested that the scattering of electrons would not be as strong if the impurities were present as ionized nanoparticles rather than as ionized atoms (Bahk et al., 2011).

Several compounds have been studied with the aim of achieving low lattice conductivities. One group that has been extensively studied is the skutterudites. The unit cell of a skutterudite is relatively open with spaces that can be occupied by loosely bound atoms that are very effective scatterers of phonons. The skutterudites form a large family of compounds, and several members have zT values of the order of unity at elevated temperature (Nolas et al., 2001). The clathrates are another family with open structures and a low lattice conductivity. It is not too difficult to find materials with zT of the order of unity above room temperature so one needs to take other factors into account in selecting generator materials. For example, various oxides have reasonably good figures of merit and have the advantage of stability. SrTiO_3 is an *n*-type material with a rather low electron mobility but it makes up for this with a high density-of-states effective mass, with zT of about 0.4 at 973 K (Zhilun et al., 2016). By way of contrast there are also organic thermoelectrics with mechanical flexibility (Zhang et al., 2014).

Recent studies have been devoted to nanostructured thermoelectric materials. The band structure is modified if the grain size is reduced to the order of the interatomic spacing in at least one direction. This could lead to an improvement in the power factor as well as a reduction in the lattice thermal conductivity. In practice it has proved to be difficult to achieve an improvement in the electronic properties for any nanostructure but there is good evidence for a reduction in the lattice conductivity (Venkatasubramanian et al., 2001).

A limit on the figure of merit

In principle there is no upper limit to the figure of merit. However, as the quantity β becomes larger the optimum Fermi level moves away from the edge of the valence or conduction band. The carrier concentration then falls rapidly. This means that zT rises only slowly with increasing β . The problem is that the Seebeck coefficient varies linearly with the Fermi energy whereas the carrier concentration displays an exponential dependence. It is not unreasonable to expect that we shall find materials that combine a glass-like phonon conductivity with a mobility-effective mass product that is close to that of electrons in pure silicon. This combination of properties would give a value of about 4 for zT at the optimum carrier concentration. However, any further improvement would be difficult to achieve.

We know that β is equal to about 0.4 for alloys of bismuth telluride with zT then equal to 1. A rise of β to about 3.2 would enable zT to climb to 4 but a further doubling of β would only allow zT to reach 5. If zT were equal to 5 the parameter M in Eqs. 1 and 2 would become close to 2.4 and $(M-1)/(M+1)$ would be about 0.4. In other words, we do not expect the efficiency of thermoelectric generators or the COP of thermoelectric heat pumps to exceed about 40% of their ideal values.

Thermoelectric modules

In principle one can obtain any amount of cooling power or generate any amount of electricity using a single thermocouple. However, this would entail inconveniently large electric currents and small voltages. Thus, most thermoelectric devices incorporate a multiplicity of thermocouples in the form of modules. A thermoelectric module consists of a number of thermoelements connected electrically in series and thermally in parallel. In theory each thermoelement can be of any length or cross-section area but it is obviously economical to make the volume as small as possible. However, when the thermoelements are very small the performance can be impaired by electrical contact resistance and by heat transfer other than through the thermoelectric material. There is a significant reduction in the temperature depression that can be achieved by a thermoelectric cooler if the thermoelements are much less than 1 mm in length.

Although most practical thermoelectric modules comprise a single stage one also encounters multi-stage devices. For example, a multi-stage thermoelectric refrigerator can be used to reach a temperature that is lower than that which can be achieved with a single stage. Also, thermoelectric generators become more efficient as the temperature difference between the heat source and the heat sink becomes larger and this may be realized by using a cascade. It is sometimes worthwhile to use graded thermoelements in which the thermoelectric properties are matched to the local temperature.

Conclusion

Thermoelectric generators and refrigerators are now recognized as practical energy conversion devices. They have no moving parts and can be adapted to handle very large or very small amounts of power. However, the reversible thermoelectric effects are always accompanied by irreversible Joule heating and heat conduction. This means that their efficiency is much smaller than that of an ideal thermodynamic machine. Their performance depends on the so-called figure of merit which is proportional to the square of the Seebeck coefficient and inversely proportional to the electrical resistivity and the thermal conductivity of the materials that form

the positive and negative branches. The best thermoelectric materials at ordinary temperatures are alloys based on the compound bismuth telluride, Bi_2Te_3 . Materials that can be used at higher temperatures include alloys based on lead telluride and silicon-germanium alloys. It is expected that the figure of merit will improve as a more favorable combination of the mobility and effective mass is found and as the lattice conductivity becomes smaller, but the efficiency and COP are unlikely to exceed 40% of their ideal values.

Abstract

Medical microrobots are tiny devices designed to perform diagnostic and/or therapy non-invasively, targeting molecules and cells at their scale. However, they should be designed based on their function and cargo transport requirements. These features are directly related to the microrobots geometry, which varies depending on the size, cargo compliance, adopted locomotion strategy, and their working environment. Geometry also affects the immunological response and the microrobots interaction with their surroundings. Here we discuss the influence of a proper microrobot design and material selection when envisioning a biomedical application, giving a particular focus to the optimization of gametes/zygotes microrobotic transport for in-vivo assisted reproduction.

Key points

- Highlight the importance of a proper microrobot design and material selection according to the intended medical application
- Evaluate how the geometry influences the efficiency of cargo transport and release, in the case of gametes (sperm and oocytes) and early embryos
 - Analyze the different reported microrobots designs for an optimal motion in viscoelastic fluids, against flow, and in contact to rough surfaces, when employing external magnetic fields
 - Identify the impact of the microrobot geometry on the immunological response

Introduction

Since it was conceived by Richard Feynman in his “There’s plenty of room at the bottom” lecture in 1959, micro/nanodevices have been devised for many high impact applications in electronics, electromechanics, analytical chemistry, and biotechnology, as well as medical microrobotics (Feynman, 1960). Microrobots are microscopic structures that convert the input energy (e.g. chemical, electrical) into mechanical motion. Microrobots can be divided into three categories based on their mode of operation: chemical, biohybrid, and physical (Medina-Sánchez and Schmidt, 2017). Chemically actuated microrobots can propel themselves by the fuel

*Equal contribution.

energy from a catalyst (platinum, silver, palladium, etc.) on microrobots reacting with liquid medium (hydrogen peroxide, organic compounds, etc.) (Gao et al., 2011; Golestanian et al., 2005; Mei et al., 2011; Paxton et al., 2004). Such toxic fuels cannot be used in medical or biological applications. Therefore, for in vivo biomedical uses, physiological fluids such as glucose, urea should be developed for the microrobot actuation (Sun et al., 2019, 2019). Biohybrid microrobots can be constructed by motile organisms such as bacteria and muscle or sperm cells with a synthetic component (Lin et al., 2022; Schwarz et al., 2017; Yang et al., 2019). They can be steered by the organisms themselves, as they move, sense and respond to biochemicals, acidity or magnetic fields. However, considering in vivo conditions, the abundance of sticky proteins may pose a big threat to the motility of biohybrid microrobots, and the motion directionality should be improved for biomedical applications as well as multifunctionality. On the other hand, physical actuation methods have been devised by various external fields such as optical, acoustic, and magnetic methods. For example, the optical method was utilized to steer phototactic bacteria and algae, but the light is poorly transparent to biological tissues. Ultrasound has not been extensively utilized for steering microrobots due to its poor reliability and reversibility but it is a method that indeed would be compatible with various imaging modalities and suitable for in vivo applications. Magnetic control holds the most significant promise because magnetic force can have efficient and fast response time as well as safe penetration to biological environments. In addition, regarding the safety, a static magnetic field under 8 T is not considered dangerous for human medical use (Schenck, 2000). To date, a variety of magnetic robots have been pursued toward the biological applications such as magnetic hyperthermia (B. Wang et al., 2018), targeted drug delivery (Schmidt et al., 2020), and minimally invasive surgery (Srivastava et al., 2016).

Physical principles of microrobots motion at low Reynolds numbers

Due to their small size, the microrobots operate in the low Reynolds numbers regime where the viscous forces dominate inertial forces. To produce a net motion in the low Reynolds number regime, microrobots must undergo a specific nonreciprocal motion. In order to design efficient microrobots, it is crucial to investigate the factors that impact their efficiency. The two main factors that influence the microrobot motion are the environment in which they operate and the microrobot geometry. Environmental factors include temperature, fluid viscosity, flow velocity, and fuel concentration. The ultimate geometry design has also proven to have an influence on the microrobot-cell interaction which could lead to an undesired immunological reaction. Finally, a selection of materials and coating is also included, being important for their final implementation in real biological environments.

To improve the efficiency of the microrobots, it is important to focus on their geometry design since the environment in which they operate is often beyond our control. By optimizing the shape and structure of the microrobots, one can enhance their performance and efficiency at achieving the intended tasks. The smart designed geometry of the microrobots provides them with different efficient modes of operation such as rolling or twisting (Bozuyuk et al., 2021; Schwarz et al., 2020; Xu et al., 2019).

The motion of the microrobots is determined by the Stokes' law which is derived from the Navier-Stokes equation for low Reynolds numbers as follows. For a simple spherical microrobot with a radius of 'r'. The Stoke' law is as follows:

$$F = 6\pi r\eta v \quad (1)$$

Where 'F' is the drag force on the microrobot, ' η ' is the fluid viscosity, and 'v' is the microrobot velocity. This law suggests that the drag force of the microrobot is proportional to the viscosity of the solution, suggesting that the velocity decreases with increasing viscosity. The parametric design in the Stokes' law is the radius of the microrobot. One way to design efficient microrobots is by using the Stokes law to calculate the drag force on the microrobots with identical radii. The drag coefficient also plays an important role for the efficient design of the microrobots. It is a dimensionless quantity that describes the resistance experienced by a microrobot as it moves through the surrounding liquid. The drag coefficient can be influenced by geometric factors such as the shape and size of the microrobot. It has been reported that the drag coefficient first sharply decreases as the ration of length to radius of the microrobot increases (Li et al., 2015). This is followed by a slight increase of the drag coefficient for higher length to radius ratios. The drag coefficient can be obtained from the following equation:

$$C_d = \frac{\frac{4\xi^2}{Re}}{(\ln \xi' + \alpha)} \quad (2)$$

Where $\xi = L/R_{max}$, $\xi' = L/R_m$, with R_m defined as the radius in the middle cross-section of a microrobot, and α is microrobot shape dependent coefficient (Li et al., 2015). By measuring the velocity of the microrobots and calculating the drag coefficient, one can optimize the design to minimize the drag force on the microrobots and develop microrobots with efficient modes of operation.

Optimization of microrobots efficiency

An efficient and viable form of motion is desired from the microrobots for practical applications. In addition to theoretical analysis, one can use numerical simulations and conduction of experiments to enhance the microrobots efficiency. This allows for a more comprehensive and practical assessment of the microrobot's performance and can lead to the development of more efficient microrobots. There have been multiple studies that combine the theoretical, numerical, and experimental approaches to tune the

shape and design more advanced microrobots which will be discussed further in this chapter. Furthermore, the size of a microrobot also plays an important role in its efficiency. Small microrobots motion are governed by the viscous forces whereas the inertial forces limit the velocity of larger microrobots. This effect was investigated in a work by Dkhil et al. using analytical and numerical methods. An optimal radius of 20 μm was found for a magnetic spherical microrobots operating in water (Dkhil et al., 2014).

Chemical microrobots

The catalytic microrobots are a sub-category of chemical microrobots, where the release of gas bubbles on the surface of the microrobots cause them to recoil and propel forward. These microrobots have been developed in three general forms of rod structures, tubular, and spherical shapes. They require different geometry improvement techniques to become more efficient.

Tubular microrobots

Bimetallic nanorods were among the first microrobots that showed the catalytic decomposition of hydrogenperoxide as a means of propulsion (Wang et al., 2006), these nanorods were later enhanced to form tubular microrobots with the vision of integrated battery and electronics (Mei et al., 2011). Further development resulted into cone shaped microrobots (Wrede et al., 2021) with increased velocities and propulsion forces (Li et al., 2014). The hydrodynamic of bubble growth in the microrobots were studied by Li et al. and a theory model was used for experimental results validation (Li et al., 2014). According to Mitrovic (Mitrovic, 1997), the asymmetry of the bubble creates a pressure difference known as a Laplace pressure. This pressure propels the bubbles along the inner wall of the tube. In a conical geometry, the asymmetry of the shape leads to the formation of a capillary force, leading to the movement of the generated bubble to the larger opening of the semi-conical microrobot (Fomin et al., 2014). It has been reported in an analytical study that when the aspect ratio ξ (Eq. 2) is held constant, the drag coefficient decreases with an increasing semi-cone angle which in turn leads to higher velocities (Li et al., 2015).

Janus microrobots

Named after the Roman god with two faces, the Janus microrobots have a two-material structure and are propelled by the catalytic reaction between the catalytic surface and the surrounding electrolyte. Since only half of a spherical Janus microrobot is coated with a catalytic layer, the bubbles are generated on this half only, which in turn propel the microrobot in a single direction. One way to enhance the speed of Janus microrobots has been reported to increase the surface roughness. The higher surface area of the rough surface leads to a higher rate of catalytic reaction which in turn leads to higher velocities (Jurado-Sánchez et al., 2015). Another approach to increase the efficiency of such spherical microrobots is to change their geometry to develop hollow spherical structures that demonstrate high relative velocities of 125 body lengths/s (Wu et al., 2012).

Biohybrid microrobots

An alternative approach to utilizing entirely synthetic microrobots, is to exploit motile biological microorganisms. In this approach the biological microorganisms are typically steered by an external stimulus to reach the desired target. Felfoul et al. used a swarm of inherently magnetotactic bacteria loaded with drug to treat tumor cells. The swarms were guided toward the tumor cells via magnetic fields (Felfoul et al., 2016). In the case of nonmagnetic organisms, polymeric caps that fit the organisms were coated with magnetic materials. It has been shown that microorganisms such as sperm cells bond to such caps. This allows the steering of such biohybrid microrobots via the magnetic field (Magdanz et al., 2013). To unload the cap from microorganisms such as sperms, Xu et al. designed a specific “tetrapod” cap that opens when the biohybrid microrobot is pushed against the target causing the sperm to release (Xu et al., 2018). To steer multiple sperm cells rather than one to increase the fertilization efficiency in assisted fertilization applications, several approaches have been proposed. Xu et al. developed a train cap to carry multiple sperm cells (Xu et al., 2020a). In another work from the same group, the sperms were immobilized on a microflake based on hyaluronic acid, and were subsequently released after reaching the target (Xu et al., 2020b). In a recent work by Rajabasadi et al., a special kind of temperature sensitive cap with multiple entries were developed to carry multiple sperms. By controlling the temperature the cap would expand and cause the release of sperms in the targeted area (Rajabasadi et al., 2022).

Physically-driven microrobots

One of the most common ways a microrobot is propelled is via magnetic fields. By making the microrobots from magnetic materials, they are responsive to magnetic field and can be moved via magnetic field gradients or other forms of magnetic fields such as a rotating magnetic field. The movement of a microrobot in a magnetic field gradient was shown in one of the earliest reports of microrobots where winged shape ellipsoids with a main symmetry axis along the long axis were designed allowing a magnetization along this axis. Furthermore, it was reported that the winged shape design decreases the side-ways drift due to the increased liquid drag along the axis perpendicular to the main axis (Yesin et al., 2005). Due to the challenges associated with the creation of a magnetic field gradient, other microrobots with alternative clever geometric designs were fabricated to move in other forms of magnetic fields such as rotating fields.

Helical microrobots

One of the most common shapes for magnetic microrobots is the helical microstructure. These microstructures resemble a corkscrew and can propel forward in viscous environments by rotating. These microrobots mimic the corkscrew movement of some bacteria such as *E. coli*. Their geometry Optimization has been studied by Johan et al. and it was found that a low number of turns of 1 to 1.5 demonstrate a better performance compared to the helices with higher number of windings. Furthermore, it was found that a triangular cross section for the helices demonstrate a higher propulsion velocity (Fig. 1A) (Quispe et al., 2019). Using COMSOL, FEM Simulations were used in this work to investigate and compute the propulsion force where it was found that the fluidic force on the microrobots follows the same trend as the microrobot velocity (Quispe et al., 2019).

On the other hand, a biomimetic approach can be beneficial for designing the microrobots since it allows the utilization of features of biological systems that have been optimized through evolution. It has been reported that in the flagellated bacteria, the mechanical coupling between the body and the flagella, plays an important role in the bacteria swimming behavior. To investigate this effect, Huang et al. (Huang et al., 2017) fabricated tubular magnetic microrobots that are connected to thin flexible artificial flagella structures (Fig. 1B). It was found that flexible flagella tail would introduce a wobbling effect on the body that causes a precession. When the helical trajectory of the microrobot body possesses identical chirality as the tail, the overall velocity of the microrobot increases.

Cilia-based microrobots

Another type of biomimetic microrobots, are the ones that mimic the cilia propulsion of microorganisms. In a work by Kim et al. (Kim et al., 2016) the cilia structures are implemented with thin hair like polymeric structures coated with Ni-Ti that allows the propulsion and steering of the microrobot (Fig. 1C). Geometry of such synthetic cilia in the form of their arrangement and beating can affect the net flow in low Reynolds numbers. The cilia arrangement has been studied by Sitti et al. (Dong et al., 2020) by computational fluid dynamics simulations and experiments. It was found that antiplectic metachronal waves could enhance the fluid flows in the low Reynolds numbers via the synthetic cilia (Dong et al., 2020).

Alternative geometries

Recently other geometries of microrobots that are propelled via magnetic fields were investigated. Among them, are microrobots that roll on the surface via rotational magnetic fields. Examples of these microrobots geometries are spiral microrobots (Schwarz et al., 2020), and rod like microrobots (Fig. 1D) (Bi et al., 2018) that rotate and roll on a surface to propel.

More complex magnetic robots were developed by combining magnetic Janus particles with soft and rigid 3D printed microstructures that act as appendages of the microrobots (Fig. 1E) (Hu et al., 2021). Another new design that has gained interest in the magnetic robotic researchers community 3d magnetization of soft magnetic structures (Goudu et al., 2020). Such soft magnetic robots can undergo complex shape changes when subjected to a magnetic field (Fig. 1F) (Xu et al., 2019a). This shape change is dependent on their magnetization during the fabrication process. Such new alternative designs add complexity to the motion and function of magnetically actuated robots and enables them to perform more intricate tasks.

Understanding the geometric factors that lead to designing more efficient microrobots for specific applications is of extreme importance. By taking the type of the microrobot into account, one can design the microrobot with geometric parameters that enable them with efficient and effective modes of operations such as twisting, rolling, and beating at high velocities and forces.

The optimization of the design and geometry of microrobots has had a huge effect on their speed and efficiency. In order for the microrobots to function properly in the body, biocompatibility and immunological reactions should also be considered. Additionally, is worth-noting that other physical propulsion methods like the ones employing ultrasound or light should be taken into account according to the intended functionality and operation environment.

Optimization of microrobot biocompatibility and their immunological response

Geometry of medical microrobots also play in important role when referring to potential immunoreactions. Our immunological system protects us from foreign pathogens and synthetic materials can affect the function of the envisioned medical devices. This phenomenon is often observed when introducing implants in the body, or for example when using nanomedicines and more recently medical microrobots. All these devices or external biological entities can trigger the activation of macrophages which can hinder the performance of such medical devices in vivo. Various strategies to overcome these hurdles have been suggested, mainly oriented to the use of specific materials and coatings. For example, cell-camouflage coatings have been employed, enzymatic and polymeric layers have been also shown to improve the circulation time of nanomedicines and some of the reported medical microrobots. More recently, other materials like zwitterionic polymers have shown to avoid their detection by macrophages over 90 h.

The morphology or geometry of the microrobots is also a key parameter to be optimized to minimize the physical interactions with cells of the immune system. Yasa et al. recently investigated the interplay between geometry and coatings of such microrobots on the immunological response (Yasa et al., 2020), they studied different variations of helical microrobot designs and put them in contact to mouse macrophages and splenocytes, freshly retrieved from mouse spleens. They found that these cells recognize these microrobots and trigger an immune response which depends on the helix turn number, with the same size, material properties and surface chemistry. These findings suggest that the microrobot geometry optimization is crucial not only to achieve optimal locomotion in physiological relevant environments but also to avoid the undesired triggering of the immune system.

Untethered small-scale robots have significant potential in broad areas, such as targeted drug delivery, (Chen et al., 2017; Mostaghaci et al., 2017; Park et al., 2017; Wang et al., 2018a) tissue engineering (Nawroth et al., 2012), minimally invasive surgery (Hines et al., 2017; Nelson et al., 2010; Ricotti et al., 2017; Sitti, 2009, 2018; Sitti et al., 2015; Wu et al., 2018), sensing and diagnosis (Chalupniak et al., 2015), by functioning in dynamic interaction with their local environment (Ceylan et al., 2019; Wang et al., 2018b). In comparison with the thermal (Le et al., 2019; Liu et al., 2012; Maeda et al., 2007), optical (Huang et al., 2015a) and electrical methods (Tan et al., 2015), the utilization of magnetic field (Abbott et al., 2009; Ceylan et al., 2019; Diller et al., 2014; Hu et al., 2018; Kim et al., 2018; Ren et al., 2019; Wang et al., 2018c; Xu et al., 2019a) is particularly promising to control the mobility and function of the robots by virtue of its ease of use, fast response time as well as safe penetration to biological environment. Compared to rigid magnetic small-scale robots, soft materials enable robots to have unique advantages regarding the flexibility and shape-changing ability. Rigid magnetic robots lack the ability to form a time-varying shape deformations since their internal structure of the body is fully confined by the homogeneous distribution of magnetic moments of the particles (Kim et al., 2013; Medina-Sánchez et al., 2016; Servant et al., 2015). Hence, these robots are limited to perform simple translational and rotational motions to reach target regions. To overcome such limitations, soft robots with programmed magnetization profile, which enables shape deformations with high spatial resolutions have been developed to achieve complex locomotion modes and functions (Abbott et al., 2009; Diller et al., 2014; Hu et al., 2018; Kim et al., 2018; Ren et al., 2019; Xu et al., 2019b).

However, magnetic soft robots developed so far are limited to define their potential aspects in biomedical applications since they are made of non-degradable polymer materials with embedded magnetic microparticles which are mostly non-biocompatible, such as NdFeB (Hu et al., 2018) and BaFe₁₂O₁₉ (Diller and Sitti, 2014) and cobalt magnets (Cui et al., 2019). To date, polymer materials used to build the backbone of the soft milli-robots (Goudu et al., 2020) including polyvinyl alcohol (PVA) (Zrínyi et al., 1998), Irogran PS455-203 (Schmauch et al., 2017), a thermoplastic polyurethane (TPU) (Mishra et al., 2016), PDMS (Huang et al., 2015b), PEGDA (Kim et al., 2011) and Ecoflex 00-10 (Hu et al., 2018) have been demonstrated to exhibit good interaction with the magnetic filler particles and allow shape changing upon interaction with the external magnetic fields. Despite the enormous recent

development in the field, such polymer materials are non-biodegradable, and not suitable to be used in biomedical applications. Hence, it is utmost importance to develop soft, biodegradable and implantable small-scale robots with properties that can fulfill the requirements of potential biomedical applications as the safety issues are becoming prominent and major concern in the field. Biodegradable materials such as CELLINK gelatin methacrylate (GelMA), collagen, silk, alginate or calcium carbonate provide sufficient mechanical support to the microrobot body. The Young's modulus of these biodegradable materials is in the order of kPa. Thus, they are very soft and adapt to the changes in the biological environment during movement toward the targeted location inside the human body. The flexibility and the shape changing ability of the robots allow them to actively pass through the biological barriers to access hard-to-reach anatomical locations in a minimally invasive manner. They also induce versatile shape deformations and undergo multimodal locomotion depending on the mechanical properties of the geometrical design, magnetization of the magnetic material, magnetization profile inside the robot body, applied external magnetic field, and the viscosity of the biological fluid. The tuning of these properties to achieve highly flexible structures at the microscale becomes challenging since it requires precise predictions of finite deformations according to the desired medical application at a clinical level. Application of magnetic fields to the fabricated robots induces magnetic torques, which creates the internal deformation of the robots due to internal magnetization profile of the robots.

Gamete/zygote transport

Microrobots, in general, are envisioned as carriers that transport various types of cargo within the organism to specific sites, improving the efficiency of the delivery process. The optimal geometry of the microrobot depends specifically on the characteristics of the cargo, the site in the body where transport and release are to be accomplished, and the specific demands of the medical procedure to be performed. The transport of gamete cells has recently attracted the attention of microrobot researchers for its application in assisted fertilization.

Gametes are reproductive cells that include sperm cells in males and egg cells in females. During fertilization, the sperm fuses with the egg cell that results in the formation of a zygote cell. Transportation of zygotes and egg cells is fundamentally different from that of sperm cells. The former are cells of several tens of micrometers that are essentially immotile and spherical, while sperm cells are motile, elongated cells whose length is barely longer than 10 μm . In general, sperm transport is more efficient when more cells can be transported, whereas zygotes and egg cells tend to be less abundant and require to be transported individually or in small numbers. Sperms, in addition, tend to be more resistant to changes in temperature and pH for moderate periods of time, whereas zygotes and egg cells are highly sensitive cells. Because of these differences, two different microrobot design strategies need to be considered which is discussed below.

Transportation of sperm cells

In the case of sperm cells, we have demonstrated the guidance and transport of motile and immotile sperm by microcarriers actuated by weak external magnetic fields, in vitro, employing biological-relevant fluids. The design of these microrobots were made to assist sperm cells in two male infertility scenarios: when sperm count is low but sperm are motile (oligospermia), or when sperm motility is low (asthenospermia). For the first scenario, designs such as cylindrical, streamlined caps, and caps with different inner cavities, have been developed (Magdanz et al., 2013; Xu et al., 2020a; Striggo et al., 2020) (Fig. 2). In case of low motility,

magnetic microhelices have been suggested as artificial flagellum which move by means of a rotating magnetic field (Medina-Sánchez et al., 2016). In both scenarios, the transport of multiple sperm cells is crucial to increase the chances of fertilization. For that, we have evaluated different approaches: first clustering individual sperm cells by employing magnetic fields, and second using protein-hyaluronic acid based microflakes which capture mature sperm (motile or immotile) (Xu et al., 2020a; Xu et al., 2020b). The last approach involves the function of in-situ sperm selection and preparation for further fertilization as it is made of hyaluronic acid which is used to select mature sperm with intact DNA. And more recently, we have shown that using 4D printed microcaps we can transport multiple sperm cells, capacitate them in situ and release hyaluronidase, an enzyme that digest the cumulus complex that surround the oocyte, to facilitate the journey of sperm and facilitate the sperm-oocyte interaction (Rajabasadi et al., 2022).

Transportation of egg/zygote cells

Likewise, for zygotes and egg cells, the first demonstration was made by Schwarz et al. using specially designed spiral microrobots to secure zygotes and egg cells inside (Fig. 3A) (Schwarz et al., 2020). The spiral microrobots are driven by rotational magnetic fields. The magnetized spiral microrobot rotates along its longitudinal axis to align its magnetic dipole moment with the external rotating magnetic field, that causes the continuous rotation of the spiral microrobot. The rotation of the spiral produces a net displacement that leads to the continuous propulsion of the microrobot. The possibility of aligning the rotation of the magnetic field in any direction in space and its frequency of rotation gives precise control over the movement of the microrobot. These microrobots have the advantage of being driven by rotating magnetic fields, which have been shown to generate more uniform motion than oscillatory or gradient fields (Liu et al., 2022). By rotating the microrobot in the vicinity of a zygote or egg cell, it is possible to capture them, and by continuing the rotation in the same direction the microrobot is propelled carrying the cell; the release is performed by rotating the microrobot in the opposite direction. The mechanism of securing the zygotes and egg cells allows, theoretically, to capture and transport of a small number of cells, although it is highly dependent on the dexterity of the user and can generate stress on the cells due to the friction they suffer in the process. Similarly, the transported zygotes and egg cells are in direct contact with the surrounding media, allowing a direct exchange of nutrients to the cells, but leaving the cells exposed to contaminants and fluid resistance. Additionally, this structure is rigid, which provides mechanical protection to the transported cells, although it may restrict the development of the zygotes.

A particularly interesting geometry for the untethered transport of individual zygotes and egg cells is the microgrippers (Nauber et al., 2023). A gripper is a particularly versatile mechanism because it allows the grasping, transport, and release of microobjects. Its structure consists of a series of flexible fingers that self-actuate in response to a stimulus. The ability of the fingers to self-fold into shape is the key to grasping microobjects. The versatility of a microgripper is based on its ability to switch between different process steps (grasp, transport, and release) at convenience, allowing it to rectify failed attempts, adapt to unforeseen situations, and be reused in different processes. The miniaturization of these mechanisms represents a series of challenges that have opened a new area of research around them, with several strategies available to activate them, however, most of them require a tethered transmission of electrical energy: electrothermal, piezoelectric, and electromagnetic actuation (Yang and Xu, 2017). In the case of untethered microgrippers, strategies based on transformable soft materials that respond to different stimuli, such as temperature, pH, or external magnetic fields, have been reported (Yin et al., 2019). Using changes in temperature and pH to actuate a microgripper in the

Fig. 3 (A) Spiral microrobot which demonstrated the cargo, transport, and release of zygotes (Schwarz et al., 2020). (B) Magnetic untethered gripper for microcargo grasping, transport and release (Gouda et al., 2020). (C) Microfluidic fabrication of cell-laden microcapsules with a liquid core and a soft shell. Reproduced from Xu J, Shamul JG, Staten NA, White AM, Jiang B, and He X (2021) Bioinspired 3D culture in nanoliter hyaluronic acid-rich core-shell hydrogel microcapsules isolates highly pluripotent human iPSCs. *Small* 17. <https://doi.org/10.1002/sml.202102219>, with the permission of John Wiley & Sons - Books.

body is complicated by the tendency of the metabolism to self-regulate and maintain homeostatic equilibrium. If this balance is disturbed, adverse reactions can occur, and the immune system can be activated. Magnetic microgrippers can be manipulated autonomously in three-dimensional space utilizing harmless external magnetic fields, allowing them to be stirred in an untethered fashion (Fig. 3B). Control over the magnitude and direction of the magnetic fields can regulate the actuation speed and applied force of the gripper, however, this control is indirect and can be optimized as including tactile sensors in these untethered microdevices remains a challenge (Liu et al., 2022). Magnetic grippers have been shown to gently manipulate biological matter and their shape and conformation can be modified according to the needs of different procedures (Jia et al., 2019). All these features make magnetic microgrippers a suitable alternative for transporting immobile cells such as zygotes and egg cells. The ability of the fingers to unfold gradually and the compatibility of the process with soft materials is optimal to allow the development of a zygote, as it can adapt to the constant increase in size, but can lead to complications of the process if the load is unintentionally released. The distance between the closed fingers of a microgripper could be beneficial for the direct transport of fluids and nutrients to the cells, however, the lack of insulation exposes the cargo to external stresses and contamination during transport. Microgrippers require precise 3D maneuverability to coordinate the gripping and delivery processes, which is difficult to achieve in complex biological environments and even more so with little or no visibility. Further studies are needed to improve the controllable motion of magnetic microgrippers, as most reports focus on their responsiveness to grip and release.

Alternatively, we propose the encapsulation of zygotes and egg cells in compartments within microrobots of arbitrary geometry. Microcapsules with a liquid core and a solid shell can be fabricated, for example, using droplet microfluidics (Fig. 3C) (Xu et al., 2021; Hennequin et al., 2009). The core could be a medium with the proper conditions to allow cell development and the shell could contain pores that allow outward molecular exchange. The shell of a microcapsule provides structural stability and support for the other components, which could include a magnetic coating or magnetic particles embedded in the structure itself. The magnetic material added to the microcapsule generates a net magnetic dipole moment. By placing this microcapsule under rotating magnetic fields, the dipole moment tends to align to the field vector, generating a magnetic torque that propels the microcapsule to tumble over the surface. The ability to control the direction of the magnetic field vector on the horizontal axis allows control of the direction of motion of the microcapsule (Yang and Zhang, 2021). The method of fabrication of these microcapsules would require considerable optimization to incorporate the sensitive zygotes and egg cells without damaging them, but once fabricated they would form a stable system optimized for the cells. The use of soft, biocompatible materials for the shell would be ideal to allow gentle interactions between the microcapsule and the environment, as well as allow zygotes to develop. The size of the capsule could be easily adapted to the number of cells desired to be encapsulated. Encapsulation of the cells would protect them from external contaminants and stresses that could be generated during transport, although it represents a challenge for the delivery of the cells to the desired site. Mechanisms of controlled degradation or fragmentation of the shell must be foreseen and optimized so as not to damage the cells in the process.

Navigating reproductive system barriers

Of equal importance is the optimization of the way in which the microrobots navigate through the various biological barriers that are found in the reproductive system. First and foremost, the microrobots must enter the reproductive system, typically through the vagina, and navigate the cervix and uterus. Navigation through these organs would be difficult due to their large size and the continuous but changing flow they are subjected to. Micromotors should be able to swim against these flows, even as the texture and volume of the fluids change. These fluids have high viscosities and may be composed of biological matter similar in size to the microrobots, such as cells and pieces of tissue, so hydrodynamic considerations must be considered to minimize the pressure exerted on the microrobot and to reduce the drag forces of the fluid. It has been shown that streamlined microrobots minimize the static pressure exerted on the microrobot, resulting in improved motility in complex media (Striggow et al., 2020; Xu et al., 2020a). A final treatment should avoid if possible the microrobot navigation through the aforementioned reproductive organs as cannulas can be used to introduce the micromotors close to the site of interest.

Depending on the treatment, some procedures would require passage through the fallopian tubes, which are a narrow and tortuous structure covered by a layer of mucus that would greatly complicate the hydrodynamic movement of the micromotors. A cannula cannot pass through this organ. In this case, mechanisms such as rolling or tumbling should be more efficient by using nearby surfaces for propulsion compared to swimming methods. These therapies should be synchronized with ovulation, when the mucosal layer thins and changes its acidity, facilitating sperm survival. In addition, contractions in the fallopian tubes are essential for sperm to navigate upward in them, and for micromotors to take advantage of these movements, they must have a resilient structure that can withstand the stress caused by these movements while being soft enough not to cause damage to the surrounding tissue. Soft biomaterials such as hydrogels are envisioned as excellent building materials for medical micromotors due to their excellent mechanical properties, resilience, biocompatibility, and ease of functionalization for the transport of molecules.

For sperm transport, the microrobots must be able to penetrate the cluster of cumulus cells and the zona pellucida surrounding the oocyte, which is normally achieved by the enzymatic dissolution of hyaluronic acid, and then open the intercellular spaces, which are mechanically enlarged until the sperm can reach the oocyte. For this, the micromotors should be loaded with hyaluronidase and designed to release it when near the oocyte, and the movement of the micromotor should exert enough pressure in the right direction to help penetrate the cumulus and zona pellucida. Hydrogels, in turn, are capable of absorbing large amounts of polar molecules due to their high-water content. On the other hand, the spiral motion has demonstrated excellent control over directional actuation and the combination of rotational and translational motion should maximize the mechanical stress applied to the barriers.

Navigation through biological matter is typically hampered by the stickiness of surfaces to which micromotors tend to adhere. In addition to optimized motion strategies and protocols, the surfaces of microrobots should be designed to minimize interactions, e.g. by pattern design or chemical functionalization of the surfaces.

Conclusion

The medical microrobots are envisioned to enable various applications such as drug delivery, microsurgery, therapy, diagnostics, and assisted fertilization. To realize such a vision, it is necessary to optimize and improve the efficiency of microrobots in terms of their speed, maneuverability, biodegradability, and biocompatibility. Since geometry can affect the efficiency of microrobots, the design and material selection play an important role in their optimization. The optimal geometry of the microrobot depends on the cargo requirements (e.g. biological cells) and the environmental properties such as viscosity and flow velocity. Three main types of microrobots have been investigated by the research community. First, the chemical microrobots, which typically use available ambient fuel to generate gas bubbles that in turn propel the microrobot. Second, the biohybrid microrobots that utilize motile microorganisms coupled with synthetic magnetic microcaps or other magnetic microstructures that allow them to be guided by external magnetic fields. The third type is the physical microrobots, which are typically driven and controlled by external magnetic fields. This kind of microrobot is of great interest for medical treatments because of its fast response and the ability of magnetic fields to safely penetrate the body and control the magnetic microrobots in deep tissues. Increasingly, microrobot researchers are turning their attention to assisted fertilization using magnetic microrobots. To accomplish this, various microrobots have been designed to transfer gametes such as sperm, and zygotes. These designs include microspirals, microgrippers, and microcapsules. Finally, to achieve in vivo assisted fertilization or embryo cargo-release using microrobots, they must navigate through the female reproductive tract. This poses additional challenges for the microrobots. For this scenario, they should be composed of soft biomaterials, capable of a high degree of internal and external functionalization, and able to deliver drugs and molecules beneficial to the medical procedure.

A smart design of such microrobots would allow them to perform multiple actuation modes such as rotational and tumbling motion. This equips the microrobots with better performance with regard to perturbances in in-vivo conditions such as fluid flows caused by heart beats, and peristaltic motions in the body.

In our opinion, many of the challenges of microrobots should be addressed by other established technologies in combination with the microrobot. This includes the delivery of the microrobot by smart catheters with capabilities to sense the environment and even help track the microrobots. Externally, the tracking methods and the magnetic field generators should be coordinated and algorithms should be implemented for enhanced navigation that is capable of learning and adapting to the obstacles.

Furthermore, to transfer these technologies to preclinical studies, initial studies of some of the spermbots have been performed in microfluidic channels containing ex-vivo oviduct fluid. We have also reported the successful tracking of magnetically driven microrobots in phantoms, ex vivo, and in living mice with high spatial and temporal resolution using infrared, photoacoustic, and high-frequency ultrasound imaging, making the first steps toward their application in living mice. However, in vitro fertilization using these microcarriers has not yet been demonstrated. Among the remaining challenges are: increasing the number of transported sperms, separating the sperm-carrying micromotors from the free-floating sperm, and finally the stability when moving from one environment to another (e.g., from one chamber to another, or from a petri dish to an ex-vivo or in-vivo organ).

In conclusion, the functions of the microrobots should be limited to the minimum to reduce the possibility of failures and to place most of the functions on external components that do not have such limitations in terms of the size and complexity of their structures as the micromotors do. This trade-off between maximizing the capabilities of the micromotor and delegating capabilities to other systems is complementary, since delegating tasks to other systems allows the micromotor to perform its tasks with greater dexterity and can also provide greater versatility in the treatment.

Acknowledgments

This work is part of the project that has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (Grant agreement nos. 853609). We would also like to acknowledge the fruitful discussions on biodegradable materials for medical microrobots with Dr. Sandhya Gouda.

Abstract

In this entry, the most important non-volatile memories used for a wide variety of applications are presented, with detailed information on their structural and functional properties. The first part addresses charge-based memories, including read-only memories, electrically programmable read-only memories, electrically erasable and programmable read-only memories, and flash memories. In a broad sense, all them can be considered non-volatile read-only memories, meaning that reading the stored information can be performed in a relatively short time, but programming and erasing require much longer times, if at all possible. The second part of the presentation encompasses non-volatile memories which exhibit similar read/write (R/W) access times, and can thus be regarded as random-access memories to all effects. More specifically, we illustrate magnetic memories, ferroelectric memories, phase-change memories and resistive memories, and discuss their future market perspectives.

Key points

- Non-volatile memory classification
- Charge-base memories
- Resistance-based memories
- In-memory computing

Introduction

The key attribute of non-volatile memory devices is their ability to retain the stored information for several years both under ON and OFF power conditions. Owing to this property, they have found widespread use in a variety of professional systems as well as consumer products. Professional systems include computers, phone exchanges, measurement setups, robotic and control systems,

[☆]*Change History:* May 2023. E Gnani and G Baccarani updated table, and Figs. 9, 11, 20, 21, 24, and 28.

automotive and medical electronics systems. Commodities and consumer products encompass smart phones, personal digital assistants (PDAs), digital video recorders, still cameras, digital TV (DTV), set top boxes, GPS-based navigation systems, toys, radio-frequency identification devices (RFIDs) and smart cards.

The stand-alone non-volatile memory market, largely dominated by flash memories, has become a sizeable fraction of the whole memory market. Therefore, dedicated technological processes have been developed to optimize their performance. The divergence of flash technology from the CMOS process, however, prevents their application as embedded memories in systems on chip. The harmonization of the two technological processes was attempted at the expense of a reduced areal density, increased number of processing steps and fabrication cost.

Non-volatile random-access memories (NV-RAM) have been investigated for a long time, but have become successful or promising products only recently. Their compatibility with the back-end CMOS process, as well as many functional improvements, make them attractive for embedded applications in systems-on-chip, or even in advanced microprocessors.

This entry is organized as follows: Section “Non-volatile memory classification” introduces the classification of non-volatile memories and illustrates their general features. Sections “Read-only memory,” “Electrically programmable read only-memory” and “Electrically erasable and programmable read-only memory” are devoted to read-only memories (ROM), electrically programmable read-only memories (EPROMS) and electrically erasable and programmable read-only memories (EEPROMS). Section “Flash EEPROM” addresses NOR and NAND-type flash memories, and is composed by five subsections devoted to: (i) flash array architectures; (ii) reliability issues; (iii) charge trap memories; (iv) multi-bit storage and, (v) three-dimensional NAND flash memories. Section “Non-volatile random-access memories” treats NV-RAMs, and contains four subsections devoted to: (i) magnetic memories (MRAM); (ii) ferroelectric memories (FRAM); (iii) phase-change memories (PCM) and, (iv) resistive memories (RRAM). Section “In-memory computing” introduces the fascinating theme referred to as “in-memory computing” (IMC). Section “Conclusion” is a summary of this entry and provides indications for future trends.

Non-volatile memory classification

Non-volatile semiconductor memories are usually classified according to their functional properties with respect to the programming and erasing operations, as shown in the flow chart depicted in Fig. 1.

Non-volatile memories can be functionally classified in two broad classes: read-only memories (NV-ROM) and read/write memories (NV-RAM). The former memories allow a relatively fast reading, but a much slower data writing into the cell, or no writing on field. The latter memories, instead, exhibit very similar and short R/W random access times, and are thus classified as non-volatile random-access memories.

Read-only memories (ROMs) are programmed at the mask level during the fabrication process by suitably interconnecting logic gates able to generate appropriate logic functions of the input data. Therefore, the reading operation is carried out by a logic computation of combinational logic circuits, which can be manufactured by a standard CMOS process. ROMs, however, suffer a lack of flexibility, which dramatically restricts their application area.

Electrically programmable read-only memories (EPROMs) are based instead on a different physical principle, and store information by controlling the threshold voltage of a special MOSFET structure with two overlapping gates, the lower of which is electrically floating. Injecting electrons into the floating gate changes the conduction threshold of the cell. A low threshold voltage

Fig. 1 Non-volatile memory classification according to functional criteria.

characterizes a conductive cell, and is associated with a logical “1,” while a high threshold voltage represents a logical “0.” The natural threshold of a virgin cell is low since the floating gate is electrically neutral; hence, it automatically stores a logical “1.” Writing (or programming) the cell, by which its content is turned into a logical “0,” means injecting electrons into the floating gate.

EPROMs can be electrically programmed on field and be optically erased by exposing the cell array to ultra-violet (uv) light. Erasing the memory, however, requires a long exposure of the cell array (~ 30 min) so that electrons confined within the floating gate can be emitted by photoelectric effect. This requires a special package with a quartz cover transparent to uv light. Quite often EPROMs are encapsulated within a standard package and used as one-time programmable ROMs (PROMs).

Electrically erasable and programmable read-only memories (EEPROMs) can be electrically programmed and erased on field, which makes them more flexible than EPROMs. A selection transistor, however, is required within the cell in addition to the EEPROM device. For a given silicon area, the increased cell size implies a smaller capacity and a higher cost per bit.

Flash EEPROMs (or simply flash) combine instead the EPROM’s cell size with the EEPROM’s flexibility and are thus largely preferred in a wide variety of applications, already mentioned in the Introduction. In flash memories, all cells of a sector are erased in parallel, which justifies their “flash” name, and re-programmed afterwards. On the other hand, reading a full page of data can be performed very quickly, which makes the long erasure time (several tenths of a second) acceptable at the system level.

NV-RAMs exploit different physical principles encompassing magnetic memories, ferroelectric memories, phase-change memories and resistive memories. With the exception of FRAMs, the above memories exhibit a state-dependent resistance value at the output, and are often referred to as “memristors.”

MRAMs rely on the resistance change of a magnetic tunnel junction (MTJ), where one of the two ferromagnetic metal electrodes has a pinned magnetic polarization and the other one has a free magnetic polarization, which represents the stored data bit. If the two polarizations are parallel, a low MTJ resistance is found. If they are antiparallel, a high resistance is detected.

FRAMs exploit the hysteretic behavior of ferroelectric materials, where electrical dipoles can be oriented in two opposite directions. Data bits are stored within a ferroelectric capacitor, and are detected by cycling the applied capacitor voltage and checking if a switch of electrical polarization has occurred.

PCMs are based on the property of chalcogenide materials to switch from a microcrystalline to an amorphous phase and back under the influence of thermal processes generated by appropriate current pulses. The data bit is thus the chalcogenide phase, detected by a resistance change.

Finally, RRAMs are based on the conductive properties of metal-insulator-metal (MIM) two-terminal devices, which exhibit a hysteretic current-voltage relationship. The low-resistance state is due to the migration of metal ions or oxygen vacancies into the insulator, forming a filamentary conductive path across the oxide. The return to the high-resistance state is achieved by breaking the filamentary metal with the application of a higher positive voltage or by applying a negative voltage, which pushes the oxygen vacancies to the top electrode interface and removes them from the oxide.

Read-only memory

Read-only memories behave functionally as encoders, for they associate an M-bit output word, which is the memory content, to an N-bit input word representing a physical address. The ROM output can always be expressed as a sum of products of the input bits. Therefore, the reading process occurs in two steps: first, a decoder, which generates the minterms of the N input bits raises high one of the 2^N word lines; next, an encoder generates the output word by OR-ing the minterms from the selection of the physical address. The output word is thus computed by activating a combinational logic circuit; hence, the content of the memory is defined at the mask level during the fabrication process, and no programming changes are possible afterwards.

In view of their functional task, the decoder is often called the AND plane and the encoder is referred to as the OR plane of the ROM. However, the logic gates used to generate both the OR and the AND planes are often NOR gates because of speed considerations. NAND gates can sometimes be used for small ROMs with some density advantage, but are unpractical for a number of input bits in excess of 4 to 8.

Fig. 2a illustrates the typical structure of the AND plane for the simple case of a two-bit structure. The p-channel MOSFETs with grounded gate act as pull-up transistors of pseudo n-MOS logic gates. Alternatively, the load gate may be connected to the clock phase Φ . When $\Phi = 0$ the bit lines are precharged high. When $\Phi = V_{DD}$ the bit lines enter a high-impedance state and can be conditionally discharged to ground if a conducting path is activated by the n-channel MOSFETs connected in a NOR configuration. Indicating with A and B the input bits and with A' and B' their complements, the output nodes of the AND plane, referred to as WL_n , ($n = 1, \dots, 4$) turn out to be

$$\begin{aligned} WL_1 &= (A' + B')' = AB \\ WL_2 &= (A' + B)' = AB' \\ WL_3 &= (A + B')' = A'B \\ WL_4 &= (A + B)' = A'B' \end{aligned}$$

where De Morgan’s theorem has been applied. Thus, the minterms of the two input bits are generated by NOR operations.

Fig. 2 NOR-based implementation of a ROM; (a) AND plane; (b) OR plane.

The OR plane, again implemented by NOR gates possibly followed by inverters, is shown in Fig. 2b. The latter realizes the following Boolean equations

$$\begin{aligned} O_1 &= WL_1 + WL_3 = (WL_2 + WL_4)' \\ O_2 &= WL_2 + WL_4 = (WL_1 + WL_3)' \\ O_3 &= WL_2 + WL_3 = (WL_1 + WL_4)' \\ O_4 &= WL_1 + WL_4 = (WL_2 + WL_3)' \end{aligned}$$

The truth table implemented by the ROM shown in Fig. 2 is represented below.

A	B	WL ₁	WL ₂	WL ₃	WL ₄	O ₁	O ₂	O ₃	O ₄
0	0	0	0	0	1	0	1	0	1
0	1	0	0	1	0	1	0	1	0
1	0	0	1	0	0	0	1	1	0
1	1	1	0	0	0	1	0	0	1

A similar procedure can be followed using a NAND implementation of the above Boolean equations.

Electrically programmable read only-memory

Electrically programmable read-only memories rely on a cell structure with two overlapping gates, as shown in Fig. 3. The lower gate is fully surrounded by silicon dioxide and is thus electrically floating. The upper gate is instead accessible and is referred to as control gate. Due to the need of two polycrystalline silicon layers and a relatively high gate oxide thickness, EPROM fabrication is not fully compatible with the standard CMOS technology.

Electrons traveling from source to drain under large gate and drain voltages can possibly achieve an energy exceeding the Si-SiO₂ potential barrier, which is about 3.1 eV. If such an electron undergoes a re-directing collision with a final momentum normal to the silicon surface, can overcome the potential barrier and be injected into the oxide conduction band. If the floating-gate voltage V_{FG} exceeds the drain voltage V_D , the field in the oxide will favor electron injection into the floating gate, where it becomes trapped. As more and more electrons are injected and trapped into the floating gate, its potential V_{FG} is lowered and the threshold voltage of the control gate V_{TC} increases.

The basic relationship connecting the floating-gate voltage V_{FG} with the charge injected into the floating gate Q_{inj} and the cell voltages is.

$$V_{FG} = \alpha_G V_{CG} + \alpha_S V_S + \alpha_D V_D + \alpha_B (V_B + \Phi_{MS}) + Q_{inj}/C_T$$

Fig. 3 Cross section of a floating-gate EPROM cell.

where V_{CG} is the control-gate voltage, V_S is the source voltage, V_D is the drain voltage, V_B is the bulk voltage and Φ_{MS} is the work function difference between the heavily doped n^+ polycrystalline silicon gate and the underlying p -doped silicon substrate. Also, α_G , α_S , α_D , α_B , are coupling coefficients expressed by the ratios of the gate, source, drain and bulk capacitances C_{GG} , C_{GS} , C_{GD} and C_{GB} with respect to the total capacitance of the floating gate $C_T = C_{GG} + C_{GS} + C_{GD} + C_{GB}$. The above equation shows that V_{FG} is a linear combination of the external voltages, with weighting factors given by the coupling coefficients, and that a negative charge Q_{inj} lowers the floating-gate voltage. When V_{FG} equals the threshold voltage for current conduction within the EPROM cell V_{TF} , the control-gate threshold voltage V_{TC} reads.

$$V_{TC} = (1/\alpha_G) V_{TF} - (\alpha_S/\alpha_G) V_S - (\alpha_D/\alpha_G) V_D - (\alpha_B/\alpha_G) (V_B + \Phi_{MS}) - Q_{inj}/C_{GG}$$

It may be seen from the above equation that the threshold voltage experienced by the control gate increases if electrons are injected into the floating gate. Strictly speaking, the gate-source, gate-drain and gate-bulk capacitances are non-linear; thus, the coupling factors are bias dependent. Quite often, however, such factors may be treated as constants. Furthermore, if $V_S = V_D = V_B = 0$, the above equation may be simplified to give.

$$V_{TC} = (1/\alpha_G) V_{TF} - (\alpha_B/\alpha_G) \Phi_{MS} - Q_{inj}/C_{GG}$$

Channel hot-electron (CHE) injection requires large gate and drain voltages to be applied to the EPROM cell, with the former higher than the latter. Thus, a large current is flowing in the channel while programming, with substantial power dissipation. This process is rather inefficient, since only a small fraction of electrons moving from source to drain is indeed injected into the floating gate, and the required time to program the cell may be as large as a few hundred microseconds. After being injected into the floating gate, electrons dissipate their excess kinetic energy by emitting phonons, and become permanently trapped within a deep (3.1 eV) potential well.

As already pointed out, native cells are conductive when the control-gate voltage is at the high level; hence, they are naturally programmed with a logical "1." Charge injection shifts the threshold voltage above the supply voltage V_{DD} , and the cell exhibits an off state when read out. Thus, the high-voltage threshold indicates a logical "0."

The former success of floating-gate EPROMs was largely due to the small cell size and the resulting high bit capacity, as well as to their on-field programmability. Erasing the content of the memory, however, can only occur by exposing the device to uv light for quite some time. This need requires a special package with a quartz cover transparent to uv light. Electrons absorbing a high-energy photon by photoelectric effect can reach an energy exceeding the Si-SiO₂ potential barrier and be ejected either into the control gate or into the silicon substrate.

The cell array organization is shown in Fig. 4. The memory cell only contains a floating-gate device with its source connected to ground, its drain connected to the bit line and its control gate connected to the word line. The source regions are shared by two neighboring cells in the same column, and so are the drain diffusions.

When the cell is addressed, the word line is raised high, and the bit line is set by the sense amplifier at a smaller voltage (about 1 V). If a substantial current flows along the bit line, the sense amplifier detects a logical "1." Otherwise, a logical "0" is revealed.

Electrically erasable and programmable read-only memory

Electrically erasable and programmable read-only memories provide a further improvement over the functionality of EPROMs by allowing the information to be electrically written and erased at the bit level. Their basic cell differs from the EPROM one in that the floating gate extends over the drain region, where a small oxide area is thinned down to a few nm to allow for electron tunneling into and out of the floating gate. This device, called FLOTOX, is shown in Fig. 5.

The physical mechanism used to program and erase the EEPROM cell is electron tunneling across the thin oxide region between floating gate and drain. In order to let electrons tunnel into the floating gate, the control gate must be biased at a large positive voltage around 15 V, while drain is kept at zero voltage.

Fig. 4 EPROM cell array organization.

Fig. 5 Schematic cross section of a floating-gate EEPROM (FLOTOX) cell.

Likewise, cell erasing is carried out by applying a large negative voltage to the control gate, while keeping the drain at zero or positive voltage. So doing, a large oxide field close to 10 MV/cm is applied to the tunnel oxide for both programming and erasing processes, albeit with opposite directions. The large field shapes the energy barrier to become triangular and reduces the tunneling distance. Fowler-Nordheim tunneling then occurs and either fills or depletes the floating gate of the formerly injected charge, thus raising the threshold voltage above V_{DD} or lowering it down below zero.

The poor threshold voltage control of an erased device, however, requires that the basic memory cell contain an additional MOSFET, referred to as selection transistor, connected in series with the FLOTOX device, as shown in Figs. 5 and 6. The drain of the selection transistor is connected to the bit line BL, its gate is connected to the select line SL and the control gate of the FLOTOX device

Fig. 6 Circuit schematics of the EEPROM cell.

is connected to the word line WL. When the cell is not addressed, the select line SL is at zero voltage, which ensures that no leakage current flows even when the floating-gate device has a negative threshold voltage.

When the memory cell is addressed, both the word line WL and the select line SL are raised to V_{DD} , thus allowing current to flow across the cell if its threshold voltage is low. Otherwise, no current flows, and the sense amplifier detects a logical “0.” In order to program the EEPROM cell, the word line is raised to the large positive voltage V_{pp} with the select line at V_{DD} , while keeping the bit line at ground potential. The V_{pp} voltage is chosen such that electron tunneling into the floating gate can occur. The bit line of unselected cells is left floating, to prevent their undesired programming. When the cell is erased, the word line is negatively biased, generating the appropriate voltage drop across the tunnel oxide. The drain of the cell is often raised high, to reduce the negative gate voltage value. To do so, the bit line is biased at V_{DD} while keeping the select line positively biased. Due to the small tunneling currents, several hundred microseconds may be required to complete an erasure cycle.

As opposed to CHE injection, tunneling is an energetically efficient process, as the electron flow is directly charging, or discharging, the floating gate. Repeated electron tunneling across the thin oxide, however, is responsible for reliability problems due to electron trapping within the oxide itself. This aging process deteriorates the oxide integrity, resulting in data retention problems and limited cell endurance.

Flash EEPROM

Flash EEPROMs are electrically erasable and programmable read-only memories. The basic flash cell is structurally similar to the EPROM's, which is essentially a MOSFET with two overlapping gates. The flash array exhibits either a NOR-type, for faster random-access, or a NAND-type organization, when high capacity and lower cost per bit are the main design goals. As opposed to full-featured EEPROMs, the selection transistor is no longer required within the basic cell structure, to the advantage of memory density. However, flash erasing can only be carried out collectively at the sector (or block) level by electron tunneling into the source from the floating gate. The typical block size is 64–256 kB in NOR flash and 16–512 kB in NAND flash chips.

An electron micrograph of a NOR flash is shown in Fig. 7. This cross section is cut along the bit line, which contacts the cell drains by vertical tungsten plugs. The tungsten silicide word line is perpendicular to the cross section and appears in the micrograph as the light rectangular area overlapping the control gate of the cell. The polycrystalline silicon gates are self-aligned; the drain regions are shared by two neighbor mirrored cells, and so are the ground-connected sources. The lateral cell extension, measured between source and drain mid-axes, is roughly 500 nm in this technology.

Cell programming is carried out by CHE injection in NOR-flash and by electron tunneling in NAND-flash array organizations. Erasing is done by electron tunneling in both architectures. In the NOR case, the erasing process is always followed by a cell-by-cell programming, with a concurrent monitoring of the threshold voltage value. In NAND-flash, instead, the negative threshold voltages resulting from the erasing process are required for memory functionality. Programming is thus performed only for “0” storing cells.

Flash array architecture

As already stated, the cell array of flash memories can be organized according to either a NOR or a NAND architecture. The former organization has a shorter random-access time, but the latter is much denser and, thus, cheaper. NOR flashes are thus required whenever a small amount of data, such as software codes, must be quickly accessed. NAND flashes, on the other hand, can read and

Fig. 7 Scanning electron micrograph of the ETOX flash cell in 0.18 μm technology. Courtesy of ST Microelectronics.

Fig. 8 Flash EEPROM cell array organization; (a) NOR architecture; (b) NAND architecture.

transfer one full data page with only one random access. Hence, they are especially used when massive amount of data must be read out and transferred with the lowest possible latency to the central memory. To date, the NAND architecture is covering a much larger fraction of the flash memory market.

The array organization of the NOR flash is shown in Fig. 8a. Cells within the same row share the word line, while cells within the same column share the bit line. Successive cells along the column are mirrored, so that one common source line is shared by two cell rows. Also, the drain diffusion is shared by two adjacent cells, to the advantage of cell size and number of contacts to the bit line. The common-source lines of a sector are shorted and kept at ground potential during a read cycle, but are raised to a positive voltage when an erasing operation takes place for the whole array sector. Because of the common source configuration of the flash cells during a read, this cell array organization is referred to as a NOR architecture.

Cell programming by CHE injection requires a supply voltage $V_{pp} \approx 10\text{--}12\text{ V}$ to be applied to the control gate and a drain voltage $V_{DS} \approx 5\text{ V}$. A special circuit called “charge pump” is used to generate the high voltage internally.

Flash erasing requires a control-gate voltage $V_{CG} \approx -12\text{ V}$, and a source voltage $V_s \approx 5\text{ V}$, while keeping the drain floating. So doing, the oxide field becomes large enough to reduce the tunneling distance down to a few nm. The negative voltage is again generated on chip by a charge pump. The use of negative voltages requires a triple-well CMOS technology, with the external p -well biased at the most negative voltage to prevent shorting of the p - n junctions with the n -layer biased at negative voltages.

Fig. 9 Typical layout of a few NOR flash and NAND flash cells (Veendrick, 2017).

The NAND array organization is illustrated in Fig. 8b. A large number of cells, typically 16 to 64, are connected in series, which allows for a compact layout and a higher density within the array due to the unique bit line contact per string and the absence of the common source lines within the array. Hence, a reduced word-line pitch becomes possible, leading to a cell size of $4F^2$, as shown in Fig. 9.

Two select transistors are present at the top and bottom of the flash column, to prevent an undesired leakage current in standby conditions. The upper select transistor connects the cell string to the bit line and the lower one to ground.

The word lines are normally biased at the supply voltage V_{DD} so that all transistors are normally on. A read operation is carried out by raising the two select lines and lowering the word line down to 0 V. In this configuration, the unaddressed cells act as pass gates regardless of their actual threshold, which is typically much smaller than V_{DD} . If the addressed cell has a negative threshold, a bit line current is detected by the sense amplifier, and a logical "1" is identified. In the opposite case, no current flows on the bit line, and a logical "0" is read out.

Reading a current through a series of several cells and two select transistors is, however, a slow operation: the random-access time is in fact of the order of 20 μ s. On the other hand, due to the inherent parallelism of the memory array, one full page of data corresponding to one word line is read out in parallel. Hence, the sequential access time is typically around 20 ns/bit, and the corresponding data rate is very large (Veendrick, 2017).

While programming a cell, the control gate is driven to a large positive voltage $V_{pp} \approx 15$ V, and the corresponding bit line is kept at 0 V. This ground potential is transferred to the source and drain of the addressed cell via the select transistors and the series of flash cells, with a negligible voltage drop due to the small tunneling currents flowing into the floating gate. The remaining bit lines must be kept at V_{DD} and the unselected word lines at a voltage $V_m \approx 10$ V, large enough to ensure a good pass-gate function irrespective of the cell threshold voltage, yet sufficiently small to prevent electron tunneling into the floating gate of the unselected cells.

This approach limits program disturbances of the unselected cells on the same word line.

To erase a sector, electrons are injected from the floating gates to their respective channels, again by Fowler-Nordheim tunneling. This process is carried out by turning on the select transistors, applying a large negative voltage to the word lines (up to -20 V) while keeping the bit lines at zero voltage. Compared with the NOR architecture, the erase operation is much faster since it does not require the successive program to "0" to be performed.

In NAND flash architectures, the required oxide field to ensure Fowler-Nordheim tunneling to erase one full block of cells is only due to the negative voltage applied to the control gates. This requires a large negative voltage generated on chip, making the charge pump less efficient. On the other hand, electron tunneling does not involve high currents, which prevents the overload of the charge pump despite the large number of cells erased in parallel.

Reliability of flash memories

Flash memories can undergo multiple program and erase cycles; hence, reliability problems are rather severe. The endurance of a flash cell is the property of experiencing multiple write and erase operations without affecting the memory performance. Connected with endurance is data retention, i.e., the property of maintaining the written data unaltered for a long time with or without any power supply.

Flash memories must typically ensure a data retention of 10 years. Hence, leakage currents must be very small even under the influence of external voltages. This implies that the gate oxide and the inter-poly dielectric must behave as ideal insulators. Therefore, the gate oxide is relatively thick ($\approx 8\text{--}10\text{ nm}$) compared with the typical gate oxide thickness of standard CMOS transistors designed for logic. The inter-poly dielectric, called ONO, is made by a silicon nitride (Si_3N_4) layer sandwiched between two SiO_2 layers, with a total thickness of $12\text{--}14\text{ nm}$.

When a NOR flash is programmed, all cells connected to the same word line are indeed subject to a large positive gate voltage around 12 V . Hence, some electrons can possibly tunnel into the floating gate from the channel, if the cell is in its conductive state, or into the control gate from the floating gate if the cell is in the off state. In the former case, the gate disturbance tends to convert a logical “1” into a logical “0” while, in the latter, the opposite occurs. Likewise, all cells connected to the same bit line experience a relatively large drain voltage around 5 V and, due to the low gate voltage, electron tunneling can occur from the floating gate into the drain. In this case, the disturbance generated by cell programming tends to convert a logical “0” into a logical “1.”

A read disturbance additionally occurs when a cell is read, despite the relatively smaller gate and drain voltages. The drain voltage heats up electrons traveling from source to drain of the addressed cell. Hence, some hot-electrons from the tail of the energy distribution can be occasionally injected into the floating gate in this case too. Due to the unlimited number of read operations, the drain disturbance must be carefully controlled. In order to prevent this effect, drain is usually kept by the sense circuitry at a voltage of the order of 1 V , well below the energy threshold for hot-electron injection. The cumulative effects of gate and drain disturbance during write and read operations can affect the integrity of the stored information within flash cells and reduce data retention below 10 years. Therefore, parity bits for error detection and correction become necessary to improve the memory reliability.

The large oxide fields needed for electron tunneling may be responsible for a degradation of the gate oxide. Charge loss in flash memories can be caused by (i) defects in the gate oxide; (ii) defects in the inter-poly dielectric and, (iii) mobile ion contamination.

The charge trapped in the tunneling oxide and the related aging effects limit the flash endurance, as the high threshold voltage of cells storing a logical “0” tends to decrease and the low threshold voltage of cells storing a logical “1” tends to increase, when the number of erasing cycles progresses, as shown in Fig. 10. The closing window between the high and low threshold voltages sets an upper limit to the maximum number of erasing cycles, which is typically about 10^5 (Bez et al., 2003). An even distribution of the erased blocks improves the memory lifetime. An appropriate control circuitry changes the physical allocation of re-written blocks to ensure such an even distribution.

The degradation of the gate oxide typically occurs due to electron trapping during the write and erase cycles. This degradation may be responsible for premature oxide breakdown or low-voltage leakage, referred to as “stress-induced leakage current” (SILC). The latter is an anomalously large current flowing across the gate oxide in a small, but significant, number of cells. SILC is due to the percolation of electrons through a string of defects located within the oxide. The percentage of cells affected by SILC is a strong function of the gate oxide thickness. Therefore, the latter cannot be scaled below 8 nm . Similar considerations apply to the inter-poly dielectric, which has a lower limit of about 12 nm . The non-scalability of the gate oxide and inter-poly dielectric, in turn, does not allow the programming and erasing voltages to be lowered, in sharp contrast with CMOS voltage scaling. Besides, the generation of large programming and erasing voltages by means of charge pumps operating at a small supply voltage is a rather inefficient process.

Fig. 10 Aging effect on the threshold voltage of flash EEPROM cells.

The SILC problem is mitigated by the provision of a redundant number of rows within the flash array. If information loss is detected in one or more cells of a row, the word line address is internally reconfigured to access one of the additional rows. With this approach, the memory functionality is re-established with a small increment of the overall chip area.

Multi-bit memory storage

The capacity of a flash EEPROM can be increased by storing two or three bits per cell, if four to eight different threshold voltages, rather than two, can be accommodated within the cell. For reliable operation, it is requested that the standard deviation associated with the statistical distribution of the threshold voltages be much smaller than the average separation between their central values. This may be accomplished with a tighter control of the injected charge into the floating gate, and with a more sophisticated reading procedure. More specifically, the threshold voltage must be monitored when programming, while the number and duration of writing pulses is controlled by a suitable logic.

The reading procedure requires a number of steps involving successive comparisons of the output current with reference currents made available by suitably pre-programmed dummy cells. So doing, the memory capacity is increased by a factor of 2 or 3 for a given array size, at the expense of a degraded access time and reduced data retention and endurance.

Charge-trap flash (CTF)

Two evolutionary approaches were pursued to mitigate the flash reliability problems by a change of the cell structure: the nanocrystal cell and the charge-trap flash (CTF) cell. In the first approach, a large number of silicon nanocrystals embedded within the gate oxide replace the floating gate. Programming and erasing are still carried out by electron tunneling across the gate insulator. The advantage of nanocrystals is twofold: first, if a leaky percolation path exists, only one nanocrystal can be affected and not the entire floating gate; next, the gate dielectric could be made much thinner, with a substantial advantage for the scaling properties of the cell. Besides, electron tunneling across a thin gate insulator is known to produce less oxide defects. The nanocrystal approach, however, was unable to generate sufficient trapping states to differentiate the high and low device threshold voltages, and is no longer pursued.

The second approach, first referred to as Silicon-Oxide-Nitride-Oxide-Silicon (SONOS) and, ultimately, Charge Trap Flash (CTF), is based on the use of an ONO gate dielectric, where the nitride layer replaces the floating gate. Electrons injected into the oxide are captured and permanently trapped within the intermediate nitride layer, raising the threshold voltage of the cell. By reversing the applied voltages, holes are injected into the nitride layer, compensating the negative charge and lowering the cell threshold. CTFs have two distinct advantages over the standard flash cell: first, a localized oxide defect, which could totally deplete the floating gate by SILC, has a little impact, as electrons are trapped in deep nitride centers and are not mobile. Next, the interaction between floating gates in adjacent cells becomes more and more important as the device dimensions are scaled down and packed more densely, possibly leading to erroneous readings of the cell content. CTF cells are instead nearly immune to such interactions and promise a more reliable operation at the lowest dimensional cell sizes.

Three-dimensional flash memories

The increasing problems related with planar flash scaling below 20 nm has triggered the development of a novel three-dimensional (3D) NAND flash architecture based on vertically oriented cylindrical gate-all-around charge trap cells, represented in Fig. 11. Such an architecture is referred to as V-NAND. The use of the third dimension, combined with multi-bit storage, makes it possible to further improve the bit density with relaxed lithography rules, reaching record capacities up to 8 Tb on chip (Micron, 2020).

The fabrication of V-NAND flash memories relies on a very complex process technology. Its detailed description, which is beyond the scope of this entry, can be found in (Veendrick, 2017). In essence, the starting point is the deposition of a large number (over 100) of alternating oxide (≈ 6 nm) and nitride (≈ 32 nm) layers. Then, vertical cylindrical holes, with 100 nm diameter, are opened by anisotropic etch, and successive layers of blocking oxide, trapping nitride, gate oxide and polysilicon channels are deposited on the lateral hole walls by the atomic-layer deposition (ALD) technique. Next, vertical trenches are opened, crossing laterally and vertically the whole structure. Horizontal nitride layers are dissolved by wet etch penetrating through the trenches, and replaced with tungsten, again deposited by ALD, forming the control gates of the individual cells. W is then removed from the trenches, in order to isolate the control gates of different layers and a dielectric is deposited on the trench walls. Trenches are subsequently filled with W again, to provide a distributed low-resistance ground connection.

Fig. 12 is an electron micrograph of the final 3D V-NAND flash structure. Vertical light plugs crossing the whole structure are the W-filled trenches, which extend in the third dimension not shown in this image. In this view, vertical cell strings appear between successive trenches, and the two light spots on the sides of each cell represent the W control gates cut along their diameters. The cell inner part appears in dark color.

In this technology, the cell height is controlled by the thickness uniformity of the nitride layers (≈ 32 nm). The equivalent cell width, measured by the inner circumference of the tunnel oxide, turns out to be about 200 nm, with a cell form factor $W/L \approx 6$, as opposed to a gate width of 14 nm with $W/L \approx 1$ for advanced planar technologies. Therefore, the cell physical dimensions are much more relaxed for the V-NAND flash, and the amount of stored charge is accordingly increased. This makes it possible to store 4 bits

Fig. 11 Cylindrical gate-all-around CTF cells for V-NAND architectures (Veendrick, 2017).

Fig. 12 Electron micrograph of a 3D V-NAND flash memory (TechInsights via EE Times <https://www.eetimes.com/first-look-at-samsungs-48l-3d-v-nand-flash/2/>).

per cell. An additional consideration is that, within a circular structure, the radial field is inversely proportional to the radius, meaning that the field is smaller in the blocking dielectric than within the tunnel oxide. This makes it possible to reduce the programming voltage from 20 to 25 V down to 15–18 V (Veendrick, 2017).

3D V-NAND flash memories are having a great market success and are now the workhorse for a wide variety of applications requiring high capacity, small cost per bit, and high data rate. To date, V-NAND flash chips containing up to 176 cell layers, 8 Tb capacity, and a data rate of 1600 MT/s are being produced (Micron, 2020). Also, solid-state disk drives with up to 16 TB capacity have become available on the market.

Non-volatile random-access memories

In addition to the read-only memories illustrated in the previous sections, which presently dominate the non-volatile memory market, different device concepts have emerged. Some of them, such as Magnetic RAMs (MRAM) and Ferroelectric RAMs (FRAM), have been around since many years, but only recently have become competitive products. These memories are based on the properties of ferromagnetic or ferroelectric materials, which exhibit a hysteretic M - H and P - E relationships, respectively. Here M is the magnetic moment and H the magnetic field; P is the electric polarization and E the electric field. MRAMs, while not being competitive in density and cost with DRAMs, have lower access times, an excellent radiation hardness, and are non-volatile. As such, they have mainly been used for military and space applications.

FRAMs are based on the properties of ferroelectric materials (Perovskite crystals, such as $\text{Pb}(\text{Zr,Ti})\text{O}_3$, shortly referred to as PZT) containing electrical dipoles oriented in either one of two opposite directions. The resulting polarization can be switched by the application of an electric field opposed to the dipole orientation. Hence, the two polarization states can be used to store one bit of information. PZT is a contaminating material requiring special precautions in the fabrication process. The recent discovery of a ferroelectric phase of HfO_2 , well established as a high- k material in CMOS and memory technologies, has further improved the commercial perspectives of FRAMs. To date, ferroelectric RAMs based on 1T-1C cells are being manufactured and are very appealing because of the simplicity of the basic cell, which promises a small size and a high density, as well as easier write operations with respect to flash memories.

A third development line is based on the use of chalcogenide materials, i.e., an alloy of Ge, Sb and Te (GST), which undergoes a phase change when heated up to high temperatures. More specifically, if a polycrystalline GST alloy is heated up to the melting temperature (about 650°C) turns into an amorphous state when it cools down. On the other hand, if an amorphous material is heated up to 500°C , it turns back into a polycrystalline state. The final state is indefinitely conserved at room temperature; hence, these materials can provide a non-volatile memory function. Due to the large resistance change associated with a phase change, it is straightforward to read the stored information by a simple current measurement.

Finally, resistive memories (RRAM) are intensely investigated due to the cell simplicity and the possibility to realize cross-point memory architectures with minimal area consumption. A resistive memory is essentially a metal-insulator-metal (MIM) two-terminal device where a filamentary path is initially created by soft electrical breakdown induced by the application of a positive voltage to the top electrode. The large concentration of oxygen vacancies or metallic ions injected from the top electrode are then driven by field-induced migration and diffusion into the insulator, where a conductive filament is formed, leading to a low-resistance state. The application of a negative voltage pushes instead those defects toward the upper electrode, re-establishing a high resistance state.

It should be noticed that MRAMs, PCMs and RRAMs are all resistive memories, despite their different physical mechanism, as the cell state is represented by a low/high resistance value. All of them can thus be classified as “memristors.” As opposed to charge-based memories, memristors offer the opportunity to treat resistances as input or output values of a computation, leading to a new computing paradigm with increased logical flexibility. This property can be exploited by an emerging discipline called “in-memory computing.” See, e.g., (Ielmini and Pedretti, 2020).

Magnetic RAM (MRAM)

Magnetic memories are based on the properties of ferromagnetic materials, such as iron (Fe), cobalt (Co) and nickel (Ni), which exhibit a non-linear hysteretic M - H relationship, as shown in Fig. 13. The residual magnetization of the above materials after the field return to zero is due to the alignment of the electron spin, which is conserved at room temperature.

Fig. 13 Magnetic moment against magnetic field in typical ferromagnetic materials.

Magnetic core memories were used in early mainframe computers, where a matrix of current carrying wires was used to program magnetic rings referred to as nuclei. Subsequent memory devices kept storing the information on magnetic elements, but the sensing scheme became entirely different, being based on the magnetoresistance (MR) effect, namely, a resistance change of a thin metallic layer due to the presence of a magnetic field. Magnetoresistance, however, is a small effect, with resistance changes of the order of 1%.

More interesting from this standpoint was the giant magneto-resistance effect, which occurs when a thin metal layer, typically Cu, is sandwiched between two magnetic films consisting of NiFe. Normally, a ferromagnetic material can be polarized at random directions. If, however, the magnetic film is narrower than the magnetic domain width, the film exhibits only two polarization states. This makes the switching threshold well defined.

When the magnetic moments are parallel, the “up” electrons do not scatter, and only the “down” electrons scatter at the interface with the magnetic materials. When the magnetic moments in the two films are in opposition, instead, both type of electrons scatter and a significant resistance increase, which can be as large as 15%, typically occurs. The effect according to which electrons with long mean-free paths travel with low resistance when the magnetic materials have parallel alignments is called “spin valve” and the discipline which investigates the spin-related material properties is called “Spintronics.”

Several different configurations of magnetic films have been proposed for data storage in MRAMs. These include: (i) the anisotropic MRAM; (ii) the Spin-Valve MRAM; (iii) the pseudo-spin valve (PSV) MRAM; (iv) the Magnetic Tunnel Junction (MTJ) and, ultimately, (v) the Spin Transfer Torque (STT) MTJ. The last cell configuration promises to become competitive with SRAMs due to its specific properties. In what follows, the MTJ MRAM cell will be first discussed, as the STT MTJ is just a simplified version of it, which improves in memory density and power consumption.

A schematic view of the MTJ memory cell is shown in Fig. 14. The MTJ contains a thin insulating layer sandwiched by two magnetic films. In the most recent implementations, the insulating layer is typically made by thin film (≈ 1 nm) of crystalline MgO, and the two magnetic films are made by a CoFeB alloy. The upper magnetic layer, called free layer (FL), is used to store one bit of information according to its polarization. The lower magnetic layer, called pinned layer (PL), has instead a fixed magnetization due to the presence of an underlying antiferromagnetic layer made by PtMn or by IrMn. When the magnetic moments of the two magnetic layers are parallel, the cell resistance is low, and a logical “1” is associated with the state of the cell. When magnetic layers’ polarizations are antiparallel, the cell resistance is higher, and a logical “0” is associated with the state of the cell. Additional metallic films can be added at the top and bottom of the MTJ to improve its properties.

The MTJ is located at the intersection of two conductors (word and bit lines) whose orientations are parallel and perpendicular to the magnetization vector. For a write operation, orthogonal current pulses I_x and I_y generate longitudinal and transverse magnetic fields H_y and H_x , respectively, whose vector sum switches the magnetic moment in the free magnetic layer.

The use of two perpendicular components of the magnetic field lowers the switching threshold of the cell, as shown in Fig. 15. This figure plots in the H_x - H_y plane the locus of the magnetic-field components at which the MTJ cell undergoes a switching. The asteroid shape of the curve indicates that, combining suitable values of H_x and H_y , allows much smaller magnetic fields (and reduced currents) to be used to the advantage of the stability of the pinned-layer polarization. The same plot indicates that the normal component of the magnetic field (easy axis field) switches the cell at a smaller field than the longitudinal component (hard axis field). The required writing currents, however, are very large and increase as the diameter of the MTJ pillar is scaled down (Apalkov, 2013).

In order to sense the cell resistance, the isolation transistor is turned on, enabling a vertical current flow across the insulating layer of the MTJ. The current is sensed by a suitable circuitry, which generates the appropriate logic level.

Non-volatility, fast switching (≈ 5 ns) and radiation hardness are the most important merits of MTJ MRAMs. On the other hand, the MTJ cell size is very large (≈ 20 – 30 F²) and the high switching currents lead to a high-power consumption. Therefore, MTJ-based memories are mainly used for military and aerospace applications. An additional problem is that the cell resistance change decreases as the operating temperature is increased, possibly leading to information loss.

The basic STT-MTJ memory cell, represented in Fig. 16, is a simplified version of the magnetic tunnel junction. The word line and the bypass line are no longer required due to the different writing scheme, so that the cell can be aligned to the drain of the

Fig. 14 Schematic view of the MTJ memory cell (Apalkov, 2013).

Fig. 15 Switching threshold locus of the MTJ memory cell (Asteroid curve).

Fig. 16 Schematic view of the magnetic tunnel junction (MTJ) memory cell (Apalkov, 2013).

isolation-transistor. The cell size is thus reduced to about $6\text{--}8 F^2$ so long as the MTJ pillar diameter can be scaled according to the minimum feature size of the implementation technology. This is no longer true for advanced technology nodes, due to the lower limit of the MTJ optimal size.

The spin-transfer torque (STT) effect is the magnetization switching in the free layer when a spin-polarized current is forced across the MTJ. The passing current causes the free layer magnetization to switch to an alignment that is either parallel or antiparallel to the pinned layer, depending on the current flow direction. This mechanism was theoretically predicted in 1996 and experimentally demonstrated in 2004 (Huai et al., 2004).

The STT MTJ cell design strives for the optimization of three main parameters: (i) low writing current; (ii) high tunneling magnetoresistance (TMR) and, (iii) good thermal stability. Here TMR is defined as $(R_{ap} - R_p)/R_p$ with R_{ap} and R_p the antiparallel and parallel MTJ resistances, respectively. Slight modifications of the basic cell structure have been thoroughly investigated, including perpendicular anisotropy, material selection and thicknesses of the free layer and the tunneling oxide. Quite often the improvement of one of the above parameters is detrimental to one (or both) of the remaining two. Besides, the optimization must account for the specific technology node. Critical aspects are temperature stability, which could possibly put at risk the MRAM non-volatility, and process uniformity, due to the extremely small MgO insulator thickness, which is only about 1 nm. The STT memory cell endurance is about 10^6 write cycles, a good figure for most applications, but no longer unlimited, due to the relatively large writing currents and the related tunneling-oxide aging process (Lee et al., 2018).

The memory organization is schematically shown in Fig. 17 (Lin et al., 2009). The horizontal word lines are connected to the gate of the access transistors. The select and bit lines are instead extended vertically and are normally set at zero voltage. When a cell is addressed, the word line and the select line are raised high and a current flows across the bit line. The sense amplifier, not shown in the figure, compares such a current with the average current experienced by two MTJs with parallel and antiparallel magnetic

Fig. 17 Cell array organization of an STT MTJ memory (Lin et al., 2009).

moments. The current mismatch is translated into a logical signal at the output. The use of twin cells to generate the reference current has the advantage to track the resistance change with temperature.

A twin cell organization, where information is always stored in two MTJ cells with opposite states, could further improve the read reliability by doubling the current difference to be detected. This read reliability improvement, however, is achieved at the expense of doubling the array area.

Embedded STT MRAMs operating in the industrial temperature range between -40 and 125 °C were successfully incorporated in a 28-nm technology and are being used for microcontroller units (MCU) and Internet of Things (IoT) applications (Lee et al., 2018).

A recent study, based on an MRAM model validated experimentally from the measurement of one million samples, has predicted a performance of the STT MTJ memory, projected to the incoming 5 nm technology node, summarized by the following figures. Read and write access times equal to 3.1 and 6.2 ns, respectively, writing current density $J_{sw} = 5.5$ MA/cm² with a pillar diameter equal to 38 nm, and a breakdown voltage of 0.99 V (Sakhare et al., 2020). Based on the above figures, the authors predict STT MRAM to become a possible candidate for last-level caches in advanced microprocessors at the 5 nm technology node.

An alternative to the STT MTJ is the Spin-Orbit Torque (SOT) MTJ with perpendicular magnetic anisotropy, where the switching current flows within a metal layer adjacent to the FL of a top-pinned (upside down) MTJ. The SOT effect was discovered in 2011 (Miron et al., 2011), and its advantages are sub-nanosecond switching and better endurance than STT MTJ. Forcing a relatively large writing current through the thin MgO layer leads to oxide degradation with adverse effects on memory endurance. Instead, decoupling the write-current from the read-current paths has beneficial effects, which become extremely important in the cache application perspective. A record switching time of 0.210 ns and endurance $>10^{11}$ cycles has been demonstrated (Garello et al., 2019). SOT MTJ memories are still in an early development stage. Their fundamental properties, however, promise exciting opportunities for high-performance innovative products.

Ferroelectric RAM (FRAM)

Ferroelectric materials exhibit a hysteretic P - E relationship, shown in Fig. 18, which can be used to fabricate non-volatile memories, referred to as FRAMs. The information is stored within the ferroelectric insulator of a capacitor in the form of an upward or a downward polarization. If a positive voltage is applied to the capacitor with an upward polarization, no change occurs in the compensating charge, and a small voltage shift is observed in the external circuit. If the polarization is downward, instead, the biased domains switch, causing a compensating charge to flow in the capacitor and the external circuit, and changing the capacitor voltage by a greater amount.

This means that the stored information can only be read by erasing the content of the memory, which must then be restored to its previous state. The conventional FRAM cells contain either two transistors and two capacitors (2T-2C), or one transistor and one capacitor (1T-1C). In the former case, the two capacitors are always biased with opposite polarizations, so that a differential reading can be carried out. Due to the obvious advantages of the 1T-1C memory cell in terms of area efficiency, only this cell will be treated in what follows. As shown in Fig. 19, the 1T-1C cell looks like the DRAM one. The FE capacitor is connected between the transistor source and the plate line (PL) which, in this case, is not at a fixed potential.

A logical “0” can be written in the cell by setting the bit line to zero, raising the word line and the plate line to V_{DD} and, after the ferroelectric material switches to a negative polarization, lowering the word line and, subsequently, the plate line down to ground. The remnant polarization will be at the lower intersection point with the vertical axis marked with 0 in Fig. 18. Writing a logical “1”

Fig. 18 Plot of the electric polarization vs. electric field for a ferroelectric material (Koike et al., 1996)

Fig. 19 Circuit schematic of the 1T-1C cell of a ferroelectric memory.

can be done instead by setting the plate line to zero, raising the word line and the bit line to V_{DD} and, after the positive polarization of the ferroelectric material, lowering the word line and, slightly later, the bit line. In this case, the remnant capacitor polarization is at the upper intersection point marked with 1 in Fig. 18. In standby conditions, the gate, drain, and plate are kept at zero voltage. The cell polarization is thus indefinitely conserved. Fig. 20 is an electron micrograph showing: (a) a peripheral memory region, (b) the FRAM region and, (c) the FE cell structure (Jung et al., 2008).

Reading is accomplished by turning the word line on while setting the bit line at 0 V in a high impedance state and cycling the plate line from 0 to V_{DD} . For a cell in the “0” state, there will be a minimal voltage change on the bit line, since the capacitor does not

Fig. 20 Electron micrograph showing: (a) Peripheral circuit region; (b) FRAM cell region; (c) FRAM capacitor. From Jung DJ et al. (2008) An endurance-free ferroelectric random access memory as a non-volatile RAM. Symposium on VLSI Technology Digest of Technical Papers, pp. 102–103.

switch its polarization. For a cell in the “1” state, there will be a much larger voltage change on the bit line since the capacitor switches its polarization and the compensating charge flows in the bit line. A voltage change at the sense amplifier input is compared with a reference voltage suitably set at an intermediate value between the expected low and high voltage levels. This switch from “1” to “0” requires a flip back of the capacitor to restore the previous state before the word line is turned off.

The use of a ferroelectric dummy cell to generate the reference voltage has the potential advantage of tracking the variations of the ferroelectric storage capacitors. However, the dummy cell would be switched many more times than the storage cells, thus generating a reliability problem due to fatigue; besides, being the dummy cell far away from the storage cells, additional factors, such as uniformity of the ferroelectric material and temperature dependence of the P - E relationship, may come into play.

A disadvantage of the R/W scheme illustrated above is due to the large plate line resistance and capacitance. PL switching is thus time consuming, and the resulting access time is about three times higher than the corresponding access time of a DRAM fabricated with a comparable technology. A different R/W scheme was thus proposed, which does not require the PL to switch (Koike et al., 1996). In this scheme, the plate line is permanently kept at $V_{DD}/2$ and only the word and bit lines are switched. This scheme requires a low coercive voltage material, like $\text{SrBi}_2\text{Ta}_2\text{O}_9$ (SBT), as the writing voltage applied to the FE capacitor is halved if the supply voltage is kept constant. On the other hand, the high-impedance sensing node may lose charge in standby due to junction leakage, leading to an unwanted switching from the “1” to a “0” state. Another read technique, called bit-line driven scheme (Hirano et al., 1997), keeps the plate line at zero voltage during a read operation, but requires PL switching for data restoration and cell writing. Hence, the access time is reduced, but the cycle time is still rather large.

A clever FRAM cell-array organization, called chain FRAM (CFRAM), is shown in Fig. 21 (Takashima and Kunishima, 1998). This scheme is formed by a chain of 8 cells, each of which is made by a parallel connection of a FE capacitor and a transistor. The plate line is connected to the common source of two central transistors and is biased at $V_{DD}/2$. Two block selection transistors (BST) connect the cell chain to the bit line. Under standby conditions, the BSTs are off and the word lines are high, thus shorting the FE capacitors, which keep their own polarization with no charge loss. When a cell is addressed, the corresponding word line is driven low and the selection transistor on the same side of the addressed cell is turned on. At the same time, the bit line is set at zero voltage. The addressed cell capacitor is thus subject to a half- V_{DD} voltage and, depending on its polarization, can inject a current in the bit line detected by the sense amplifier.

The present scheme overcomes the two major problems of the conventional 1T-1C cell array organization. First, the cell size can be made as small as $4F^2$ with stacked capacitors as for DRAMs. Next, all FE capacitors are short-circuited by the corresponding transistors. Hence, junction leakage does not affect the cell state, and refresh is no longer required. Moreover, it achieves fast non-driven half- V_{DD} cell-plate operation, and reduces the bit-line capacitance to about one-quarter of the conventional one. Finally, random access is possible. A practical implementation of the chain FRAM led to the development of a 128 Mb memory chip with a 1.6 GB/s double-data rate (Shiga et al., 2010).

The FRAM read access time is of the order of 70 ns, quite comparable with that of early DRAMs, but considerably slower than the access time of state-of-the-art DRAMs, which is currently around 14 ns. The write access time is around 100 ns, i.e., much faster than the write operation of a flash memory. Likewise, the write endurance of the FRAM, which ranges between 10^8 and 10^{12} cycles depending on the ferroelectric material, is much better than the endurance of commercial flash memories.

The recent discovery of an orthorhombic HfO_2 phase with ferroelectric properties made it possible to develop ferroelectric FETs (FeFET), as shown in Fig. 22, where an FE layer is integrated in the gate stack (Dünkel et al., 2017). This device, fabricated with a 22 nm SOI technology, can embody by itself a simple 1T memory cell with the conventional gate, source and drain connections to the word, plate and bit lines, respectively, and is fully compatible with the 22 nm SOI CMOS technology for logic. The reported

Fig. 21 FRAM cell array organization (Takashima and Kunishima, 1998).

Fig. 22 Cross section of a ferroelectric FET fabricated in a 22 nm SOI technology (Düinkel et al., 2017).

endurance was only 10^5 cycles, but performance improvements are expected in the near future. Therefore, the FeFET is a candidate for the development of low-cost high-performance embedded non-volatile memories.

Phase-change memories (PCM)

Phase-change memories (PCMs) are based on peculiar properties of chalcogenide materials, i.e., compounds often based on germanium, antimony and tellurium, namely, $\text{Ge}_2\text{Sb}_2\text{Te}_5$ (GST), which is the most frequently-used material for PCMs. Different compounds are often used for optical applications in CDs, DVDs, and Blu-Ray disks. Memory switching in these materials is primarily a thermal process, which involves a phase transformation from a polycrystalline to an amorphous state, and vice versa, under the influence of a heat source. When the heating process stops, the material retains its new state, thus exhibiting memory. In practice, this transformation is obtained by passing a constant current pulse through the sample for an appropriate time. The resistance change between the two states is about 2–3 orders of magnitude, so that reading can easily be accomplished by low-bias non-destructive detection of the cell resistance.

A schematic cross section of two PCM cells is shown in Fig. 23. The cell core is basically given by a crystalline GST layer located between a vertical resistive heater and a horizontal metal line (bit line). The vertical resistor is connected to the emitter of a p-n-p bipolar transistor, the base of which is connected to the word line. In a process variant, the access transistor can be a MOSFET, rather than a BJT.

In order to let a phase change occur, the GST layer is heated by a current pulse by Joule effect. An intense, but relatively short, current pulse raising the local GST temperature up to the melting point of about 650°C , followed by fast cooling, turns the polycrystalline material into an amorphous high resistance state within a mushroom-like volume above the heater (reset). A longer, but less intense, current pulse heating the material up to about 500°C turns it to a polycrystalline, low resistance state (set). The

Fig. 23 Schematic cross section of two PCM cells.

current levels and the time duration of the current pulses depend on the thermal capacity of the GST layer. Hence, scaling down the GST volume is a primary objective of PCM design to reduce random access time and energy consumption.

An obvious concern of this technology is the thermal cross talk between adjacent cells. In principle, the local heating of the GST layer up to the melting temperature during a reset could spread around heat and, possibly, set a neighbor cell. Thermal simulations, however, seem to indicate that this is not the case, and that no appreciable thermal crosstalk would in fact occur down to the lowest technology nodes of the ITRS. This is mainly due to the linear scalability of the reset current with the contact area for a given cell geometry. If all physical dimensions of the cell are scaled down by a common factor κ , instead, one would expect the set and reset resistances, as well as the thermal resistance, to increase by the same factor κ , and the programming currents to decrease by κ at constant voltage.

The advantages of PCM memories are manifold. First, the additional processing steps required to deposit the GST layer and delineate the cell geometry can be performed in the back end of the fabrication process, and do not interfere with the front-end CMOS technology.

Compared with flash memories, PCMs exhibit a much lower random access time, low set and reset voltages, and fulfill the 10-year retention requirement. In addition, memory endurance can be made as high as $\approx 10^{12}$ S/R cycles with an appropriate cell design and with a Sb-rich chalcogenide material (Kim et al., 2016).

Combined with a two-terminal ovonic threshold switch (OTS) device, resistive memories like PCMs can be arranged in a cross-point architecture, which provides the highest possible density with a cell size equal to $4F^2$ (Kau et al., 2009). Fig. 24a shows an electron micrograph of the PCM cell with the OTS selection device. Fig. 24b represents a cross-point array architecture sandwiched between the M2 and M3 metal layers (Karpov et al., 2010). Also, multi-layer 3D memories can be manufactured with this technology.

Stand-alone PCMs were produced as of year 2008. The latest product is Intel's Optane M15 solid-state drive, referred to as X-point (Le Gallo and Sebastian, 2020). The chip fabrication technology has not been disclosed, but is widely supposed to be a PCM-OTS. Optane, announced in year 2018 and distributed in 2019, is based on 128 Gb 3D memory chips. The disk drive maximum capacity is 64 GB; the read and write latencies are 6.75 and 12 μ s, respectively, and the sequential R/W rates are 2000 and 900 MB/s. Its maximum throughput is still lower than that delivered by high-end NAND flash SSDs with high queue depths, but the write random access time is considerably shorter due to the simpler writing scheme of PCM memories.

The scalability of the PCM cell, the elimination of the large voltages required by flash memories, the reduced set and reset times and the addressability of every single cell make the PCM memory technology an interesting candidate for low-voltage, high-density, low-cost, future-generation products.

Resistive RAM (RRAM)

The physical structure of the resistive memory cell is a metal-insulator-metal (MIM) device with a top electrode (TE), a bottom electrode (BE) and a metallic oxide in between. The initial low-voltage resistance is thus very high, due to the presence of the insulating layer. This is the high-resistance state of the cell, corresponding to a logical "0." The application of a positive voltage to the TE can start a soft breakdown, generation of defects such as oxygen vacancies, and a migration of metallic ions through the insulator. A conductive filament is thus formed that crosses the oxide and reaches the BE and a low-resistance state is eventually obtained, corresponding to a logical "1." The reset operation is carried out by the application of a negative voltage, which pushes those oxygen vacancies toward the upper electrode, re-establishing a high resistance state. This kind of cells is called "bipolar." As an alternative, some cells are reset by the application of a higher positive voltage, due to the breaking of the conductive filament, which behaves in this case as a fuse.

Fig. 24 (a) Scanning Electron Micrograph of a PCM cell with a chalcogenide selector device; (b) PCM cross-point array sandwiched between M2 and M3 metal layers (Karpov et al., 2010).

Fig. 25 RRAM stacked cross-point architecture (Liu et al., 2014).

The resistive cell may, or may not, be accompanied by a selection device connected in series with it. In the latter case, however, sneak currents severely limit the array size. For larger memory blocks, an access device is required. In order to maintain the minimum size of $4F^2$, and the related area efficiency, a diode-like two-terminal device must be chosen, even if a three-terminal FET could improve the reading uniformity of the addressed cells. Another motivation to exclude transistors is that a multi-layer cross-point architecture can be fabricated in the back end of the process. Fig. 25 shows a sketch of a two-layer structure, with the bit lines shared by the upper and lower layers and separate word lines at the top and bottom of the structure. Fig. 26 shows a practical implementation of the two-layer concept in a 32 Gb RRAM (Liu et al., 2014).

Resistive memories are scalable and CMOS-compatible, and their fabrication technology has been integrated into foundry processes. Open research problems for these devices are still a better understanding of their set/reset physical mechanisms and reliability issues.

The array organization is a cross-point scheme with resistive cells connected at the crossing between vertical bit lines and horizontal word-lines. Actually, the function of horizontal lines differs from that of standard word lines, as the access device is a two-terminal diode and is not driven by the word line. The read operation is illustrated in Fig. 27 (Liu et al., 2014). For a read operation, the selected bit lines and the unselected word lines are biased at the same voltage V_{read} , while the selected word lines and unselected BLs are biased at the unselected BL voltage $V_{\text{UB}} < V_{\text{read}}$. The selected cells, denoted with S in Fig. 27, are biased between the V_{read} and V_{UB} voltage levels and conduct some current. With this biasing scheme, the half-selected cells on the selected BLs (F cells) and the half-selected cells on the selected WL (H cells) are nominally biased at 0 V. The unselected cells (U cells) are reverse biased between V_{read} and V_{UB} , and they conduct a small current due to the reverse biased access diodes and the low bias level. The H and F cells are targeted to have zero bias but, due to parasitic resistance in a large array, a voltage offset from the power supply grid and the circuitry can create a nonzero bias across those cells.

The program operation is performed by driving the selected BLs to the V_{WR} voltage and the selected WL at zero voltage (Fig. 28). The unselected cells are reverse biased between the unselected word line voltage V_{UX} and the unselected bit line voltage V_{UB} . The half selected cells connected to the selected BL and those connected to the selected WL are forward biased below the disturb level and conduct current along the selected BL or the selected WL. These currents cause a voltage drop, which reduces the write voltage across the selected cell.

Fig. 26 Resistive memory cross-section showing two layers of RRAM cells above the supporting circuitry (Liu et al., 2014).

Fig. 27 Reading scheme of a resistive RAM (Liu et al., 2014).

Fig. 28 Writing scheme of a resistive RAM (Liu et al., 2014).

A compensation scheme is implemented to account for the above parasitic effects. In essence, the sense amplifier samples the leakage currents in the bit lines before the write pulse is asserted, and generates the compensation currents to be injected into the bit lines. The WL pulse amplitude is then established according to the required programming target voltage. Without this compensation scheme, the program pulse could fail to switch the cell as desired (Liu et al., 2014).

In-memory computing

The large computational burden required by the management of big data and artificial intelligence (AI) problems, such as the control of autonomous systems, poses serious challenges to the traditional Von Neumann computer architecture. Data transfer from memory to CPU and back represents a well-known bottleneck, which degrades latency and additionally consumes thousand times more energy than that strictly required for the computation itself. The concept of transferring computation into memory, rather than doing the opposite, has thus emerged. An entirely new discipline, referred to as “In-Memory Computing” (IMC), investigates possible approaches to the above problem, identifying innovative solutions and new avenues to system development.

In principle, IMC can be performed using either charge driven memories, like SRAM, DRAM and NOR flash, or resistive memories, such as RRAM, PCM, and MRAM (Sebastian et al., 2020). Resistive memories, however, offer the opportunity to consider resistance values as input or output data of a given operation, which extends the flexibility of traditional logic functions by introducing implication (IMP) (Borghetti et al., 2010) and threshold logic function (Ielmini and Wong, 2018). A new computing

paradigm is thus introduced. An additional advantage of RRAMs and PCMs is the opportunity to arrange cell arrays in a cross-point configuration, minimizing the overall area occupation.

Detailed investigations were carried out on the entire architecture, including crossbar and CMOS controller, required for data-intensive parallel addition (Nguyen et al., 2017). This study led to the conclusion that the IMC parallel adder improves area and energy consumption by at least two orders of magnitude, compared with a multicore parallel adder.

Both digital and analog computations are possible with a suitable supporting circuitry. Analog computation takes advantage from the natural addition of currents injected into the same node (Kirchhoff current law) and the natural multiplication expressed by Ohm's law, namely, $I = GV$, where I is the current, G is the conductance of the memory cell and V the applied voltage. Matrix-vector multiplication can thus be obtained if the memory array $||G||$ stores the matrix data and $||V||$ represents the input vector. The resulting output currents are thus

$$I_j = \sum_k G_{jk} V_k.$$

This computation can be carried out by a matrix of conductances connected between horizontal lines at the voltage V_k and vertical lines connected to the inputs of operational amplifiers with a constant feedback resistance. Different array architectures can be used to solve linear systems and regression problems (Ielmini and Pedretti, 2020).

As is well known, analog computing is affected by noise and by the limited accuracy of the conductance matrix entries. Therefore, the obtained results can be converted to digital form and sent to a digital solver running an iterative solution algorithm. Due to the excellent accuracy of the first-order solution, very few iterations suffice to reach convergence (Le Gallo et al., 2018).

Conclusion

In this Encyclopedia entry, non-volatile random-access memories are presented, with special emphasis on cell structure, array organization, R/W and erase approaches and applications. The stand-alone non-volatile memory market is presently dominated by 3D flash memories in NAND configuration, which exhibit record density and capacity, low cost per bit, high data rate and long retention time. Possible drawbacks are the dedicated process technology, which makes them unsuitable for embedded applications in systems-on-chip, a moderate endurance and a poor random access time. It should be noticed that floating-gate cells, which have been the flash workhorse for a long time, are no longer used in 3D memories to the advantage of charge trap cells in vertical-configuration flash memories.

Several memory types, based on different physical principles, have been deeply investigated, leading to the development of more or less successful products. Among them, magnetic RAMs, which exhibit the best radiation hardness, high endurance and short switching time, were mainly used in the past for military and space applications. The later development of the STT-MTJ memory has considerably improved some weaknesses of early magnetic RAMs, including cell area, high switching currents and compatibility with back-end CMOS process. To date, the most advanced STT-MRAMs are expected to compete with static RAMs for last-level cache applications at the 5 nm technology node (Sakhare et al., 2020).

Ferroelectric RAMs have been developed since the mid-nineties. Their potential advantages are fast switching time, long endurance, and relatively small 1T-1C cell area (comparable with that of DRAM cells). Clever array topologies and reading procedures were conceived to improve the access time. The recent discovery of a FE phase of HfO_2 made it possible to develop ferroelectric FETs at the 22 nm technology node by directly incorporating the FE HfO_2 in the gate stack (Düinkel et al., 2017). With this approach, the FE cell is reduced to just one transistor fully compatible with the CMOS process. Dense memories can thus be expected to be developed for embedded applications by exploiting such a new type of cell.

Among the relatively new non-volatile memory types, the phase change memory is one of the most successful. Strong points of this memory type are retention time, endurance and moderate random access time for read and write processes (70–100 ns). Compatibility with the back-end CMOS process makes the PCM RAM especially suitable for embedded applications in systems-on-chip.

Stand-alone PCM memories were developed in the last decade, leading to the Octane M15 solid-state drive, which exhibits a capacity ranging between 16 and 64 MB, sequential R/W up to 2000 and 900 MB/s, respectively, and R/W random latencies up to 6.75 and 12 μs . The specific materials used for the memory cell and the access transistor of the 3D X-Point™ chip were never disclosed, but it is widely believed that these materials are two different types of chalcogenide, along the lines of previous papers (Kau et al., 2009). The chip capacity is 128 Gbit and the array organization is known to be a two-level cross-point. This product represents an additional memory level in the computer memory hierarchy, which complements DRAMs with its non-volatility and improves the responsiveness of computers with a traditional flash-based SSD.

Further developments to compete with vertical flash memories in capacity appear to be unlikely, due to a possible PCM limitation in the number of stacked layers. Likewise, the hope to replace DRAMs with a “universal” PCM memory, turned out to be unsuccessful. State-of-the-art SDRAMs exhibit a latency around 14 ns, well below the R/W access time of PCMs.

Resistive memories are in an advanced development phase, but the set/reset mechanisms are not fully understood. An important achievement has been the successful fabrication of a 32 Gb test chip (Liu et al., 2014). No information is provided on the specific cell materials and selection device. The block size is much increased with respect to previous RRAM implementations by a careful control of sneak currents. As for other resistive RAMs, stand-alone implementations are unlikely to become competitive with vertical

flash memories. On the other hand, smaller-capacity embedded RRAMs can possibly be incorporated in systems-on-chip due to their compatibility with the back-end CMOS process. Finally, they are the subject of many investigations for IMC, due to the cell simplicity and the small area occupation of the cross-point architecture.

Abstract

In this Encyclopedia entry, volatile random-access memories used for a wide variety of applications are presented. More specifically, the structural and functional properties of static and dynamic RAMs, including cell topologies, cell array organizations, reading and writing procedures, reliability issues and typical applications are illustrated with a detail compatible with the allowed entry size. Content addressable memories are also treated in the final part of this entry. Conclusions and future trends complete the presentation.

Key points

- Volatile memory classification
- Static random-access memory
- Dynamic random-access memory
- Asynchronous and synchronous RAMs
- Content addressable memory

Introduction

Modern computer architectures rely on a hierarchy of memories, which differ in access times and density. The higher speed is typically achieved at the expense of a larger cell area, smaller memory capacity and, thus, higher cost per bit. At the upper levels of the hierarchy, we find registers, which are deeply rooted within the logic circuits of the processor, and three levels of cache memory. Caches typically employ static random-access memories (SRAMs) based on six transistors per cell. At the next level, the computer central memory uses dynamic random-access memories (DRAMs) based on cells comprising only one capacitor and one transistor. At the lower levels of the hierarchy, one finds several mass-memory devices, namely: solid-state drives or magnetic disks, optical disks, and flash memory cards. Magnetic tapes are used to archive large amount of data to be seldom retrieved. As opposed to static and dynamic RAMs, which

are volatile memories, mass-memory devices are non-volatile, i.e., they retain the stored information upon power loss or shutdown. This is an essential requisite, which allows information to be safely stored and retrieved whenever necessary.

Memory devices have found widespread use not just within computers and smart phones, but also in a variety of professional systems, such as telecommunication networks and phone exchanges, robotic and control systems, automotive and medical electronics systems, as well as commodities and consumer products, including personal digital assistants (PDAs), digital video recorders and still cameras, digital TV (DTV), set top boxes, GPS-based navigation systems, toys, and smart cards. Despite this wide variety of applications, which require a different throughput, latency and power consumption, and the related diversification of the memory market, we shall concentrate in what follows on unifying factors, such as basic physical principles, and general architectural features, which allow us to treat this subject within the constraints of a tutorial presentation.

This treatment specifically addresses semiconductor memories (mass memory devices based on magnetic and optical storage are discussed elsewhere within the Encyclopedia) and is split in two parts: part I is devoted to volatile memories, which are at the highest levels of the hierarchy in view of their excellent performance and unlimited endurance; part II is devoted instead to non-volatile memories, which are being used when the non-volatility is an essential requisite of the application.

The classification of semiconductor memories is presented in the next section. Section “Volatile memories” discusses the general features of volatile memories and defines the most important performance-qualifying parameters. Reliability issues related with soft error rates are also mentioned. Section “Static random-access memory” provides detailed descriptions on structural and functional SRAM properties, including basic cell topologies, cell array organization, sense amplifier structure and typical applications related with access time, power consumption and reliability issues. Section “Dynamic random-access memory” is devoted to the structural and functional DRAM properties. It contains the description of the one-transistor, one-capacitor memory cell, the organization of the cell array, the structure and operation of the sense amplifier and the fundamental DRAM architectures, namely: asynchronous, synchronous, Rambus and Video RAM (V-RAM). A short description of the capacitorless DRAM cell is finally provided. Section “Content-addressable memory” illustrates the 10-transistor cell structure. Next, the operation of associative memories, as well as their basic application as tag memory of set-associative caches is briefly outlined. Concluding remarks and future trends about volatile memories and their main applications areas are made in Section “Conclusion”.

Memory classification

Semiconductor memories can be classified according to both structural and functional criteria. Following the latter approach, they are split first into volatile and non-volatile memories, as indicated in Fig. 1. As pointed out in the Introduction, volatile memories do not retain the stored information if the power supply is turned off, while non-volatile memories do retain the stored information in the above conditions. Also, volatile memories can be written and read on field in very short times. Non-volatile memories, instead, can only be read on field in short times, whereas repeated programming and erasing operations may not be possible or, if possible, typically require much longer times. Different physical approaches are used to store information in the above memories.

Most volatile memories are randomly accessed and are thus referred to as random-access memories (RAM). Sequential memories, where bits are written and read sequentially, are only used for specific applications, being outperformed by RAMs both in terms of speed and power consumption.

Content-addressable memories (CAM) are functionally and structurally different from RAMs. In the latter memories, every single bit, byte, or word can be accessed from the knowledge of its physical address. CAMs are instead addressed by an associative search using a data word as input and provide an address as-a-result of this search.

Fig. 1 Semiconductor volatile memory classification according to functional criteria.

Volatile memories store the information either statically (SRAM) or dynamically (DRAM). In the former case, the storing mechanism is based on a regenerative circuit characterized by two stable states. In the latter case, information is stored as a charge on a capacitor.

Static RAMs use a basic cell containing either six or four transistors per cell. The former type of cell is obviously larger, but is compatible with the standard CMOS technology, and is typically used for fast embedded memories employed in first, second and third-level caches. The latter type requires a thin-film transistor (TFT) technology not compatible with the standard CMOS process. It provides a higher density and was preferred in the past for large, stand-alone third-level caches outside the processor chip. To date, device miniaturization makes it possible to integrate third-level caches on chip, with huge performance advantages in terms of speed and power consumption.

Dynamic RAMs may be characterized by different architectures. In the past, DRAMs used to be only asynchronous, and could start a memory cycle whenever three external commands referred to as row-address strobe (RAS), column-address strobe (CAS) and write enable (WE) were successively asserted. More recently, the need to improve the cycle time and the throughput of DRAMs has suggested more sophisticated architectures, which operate synchronously under the control of the system clock. The synchronous DRAM (SDRAM) is the most widely used memory architecture. A variant of the SRAM is the Rambus DRAM (RDRAM), by which a careful design of the memory board allows for very large clock frequencies.

Volatile memories

The most important parameter characterizing the memory performance is the access time, i.e., the time elapsed between a read request and the availability of the requested word. The cycle time is instead the minimum time between two successive read requests; its inverse is the memory throughput. The access time of embedded SRAMs may vary from one to several ns, depending on the memory size and the resulting capacitances of the word and bit lines. Therefore, these memories are used at the highest levels of the hierarchy within advanced computers, PCs, and smart phones.

DRAMs feature the smallest bit size and are typically used for the computer central memory. To date, a central memory of 8–16 GBs is common practice for desktop, portable PCs and cell phones. Servers or mainframes typically employ several hundred GB of central memory; hence, the one-transistor DRAM cell is by far the most-largely produced semiconductor device in modern Industry. Under the assumption of an average main memory of one GB and a worldwide production of 100 million computers/year, and even more cell phones, it turns out that $\approx 10^{18}$ DRAM cells are manufactured every year. The access time of DRAMs is of the order of 40 to 60 ns. Therefore, accessing data stored within the central memory of a computer requires several tens of clock cycles for a modern processor.

Volatile memories can suffer data loss due to soft errors, which are caused by the interaction of energetic nuclear particles, such as α , β and cosmic rays, with the silicon substrate. These events may occur due to the radioactive decay of some impurity atoms contained within the package material and/or the metal layers of the memory chip. Alternatively, as for cosmic rays, these energetic particles may come from the outside space and occasionally hit the memory device. A charged energetic particle penetrating through a semiconductor substrate generates many electron-hole pairs, which are then separated by the electric field within the device active region. These carriers can possibly compensate the charge stored within a cell capacitor and modify its state. Even static memories are not immune to soft errors, for an energetic particle impinging onto a bi-stable circuit can upset it and change its state. In both cases, a soft error would occur.

In-order-to ensure the full reliability of the system, several strategies are pursued. At the device level, the geometry of the active region is designed in such a way as to drain excess carriers generated by the energetic particle by reverse-biased p-n junctions, so that the charge stored with-in a cell capacitor can hardly suffer a substantial change; also, the word bits are not stored at consecutive physical locations, so that at most one bit of a word can be changed due to the occurrence of a soft error. At the system level, a few more parity bits are stored together with a 32- or 64-bit word. When a word is retrieved from the memory, the examination of the parity bits makes it possible to detect the occurrence of one or more soft errors and correct the wrong bit.

Static random-access memory

The simplest bistable circuit is obtained by cross-connecting two CMOS inverters M1-M2 and M3-M4, as shown in Fig. 2. Clearly, such a circuit can be biased in either one of two states, characterized by $V_{o1} = 0, V_{o2} = V_{DD}$ or $V_{o1} = V_{DD}, V_{o2} = 0$, respectively. By associating the logical value “0” to the former, and the logical value “1” to the latter bias condition, we store one bit of information within such a circuit. So long as the power supply is on, this cell will indefinitely preserve the stored information. Hence, the definition of static memory.

In-order-to access the information, however, two more devices M5 and M6 are needed within the cell, as shown in the same figure. These devices act as pass transistors, which isolate the cell if the word line is low or connect the cell to the bit lines if the word line is high. Hence, the total number of transistors per cell is six. The bit lines, which are shared by all cells within the same column, provide the read-out information to the sense amplifier, i.e., the circuit which generates a logical output data from a slight unbalance of the bit lines.

In four-transistor memory cells, the pull-up MOSFETs M2, M4, are replaced by either passive resistors, as shown in Fig. 3, or thin-film transistors (TFTs) made by polycrystalline silicon. In both cases, pull-up devices are laid out on top of the n-type transistors, with an area saving of about 30%. In the former case, the resistance R must be very large, since the stand-by current

Fig. 2 The six-transistor CMOS SRAM cell.

Fig. 3 The four-transistor CMOS SRAM cell.

consumption of the cell is given by V_{DD}/R . The resistance value is thus defined according to the need of supplying the minimum current to preserve the high voltage of the node. In practice, $R \approx 1\text{--}10\text{ G}\Omega$, which can be achieved using a second layer of a lightly doped polycrystalline silicon film. The use of TFTs as pull-up devices reduces the leakage current by nearly two orders of magnitude with respect to the passive resistor cell and improves the current drive capability of the pull-up devices in the on-state.

This improvement can be achieved at the expense of a more complex technology, involving an additional masking step, and the deposition of an undoped polycrystalline silicon film. It was thus used only for stand-alone memories, which are now seldom used.

Cell array organization

The cell array of an SRAM is schematically organized as indicated in Fig. 4. A row decoder receives at the input the row address of the required word and raises the corresponding word line high. Hence, all cells pertaining to the above row become connected to their respective bit lines.

The output multiplexer acts as a column decoder, and selects the appropriate bit, byte, or word. The corresponding bit lines are then connected to the sense amplifier(s), which detect the stored information within the selected cells. If the depth of the column decoder is too large, it may be worth interposing one sense amplifier between a first partial column decoder, acting on the bit lines which carry analog signals, and a second column decoder acting on the digital outputs of the sense amplifiers. Clearly, reducing the number of sense amplifiers is an advantage from the standpoint of power consumption but, on the other hand, interposing too many pass transistors between the bit lines and the inputs of the sense amp could be detrimental to the accuracy of the readings.

It should be noticed that, if the row decoder receives a K -bit address and the column decoder gets an L -bit address, the array contains 2^K rows and 2^L columns. Thus, a total number of 2^N cells is present within the array, with $N = K + L$. The number of selected outputs m depends on the memory organization: if the SRAM is fully decoded, $m = 1$. In this case, one single bit is read from, or written into, the array. Alternatively, m can be either 8 (byte decoding), 16 (half-word decoding) 32 (word decoding) or 64 (double-word decoding).

Cell reading and writing

A reading cycle proceeds as follows: (i) the bit lines, pre-charged at V_{DD} , are turned to a high impedance state; (ii) The word line is raised, thus connecting the cells within the addressed row to the bit lines; (iii) The pull-down transistors of the addressed cells discharge one of the two bit lines, while leaving the other at V_{DD} ; (iv) The selected bit lines are connected to the sense amps via the

Fig. 4 SRAM cell array organization.

column decoder; (v) The sense amps read the content of the addressed cells and make the bit information available to the output circuitry; (vi) The row and column decoders are reset; (vii) The bit lines are reset to V_{DD} .

Likewise, a writing cycle proceeds as follows: (i) The row and column decoders are activated, thus connecting the addressed cell to the respective bit lines and the latter to the output circuitry; (ii) One of the two bit lines connected to the cell is discharged to zero; (iii) The bit line connected to ground either confirms the status of the cell or upsets the cell in order to make it biased according to the desired input; (iv) The row and column decoders are reset; (v) The bit lines are pre-charged to V_{DD} . The timing of the above operation sequence is controlled by internally generated signals.

Sense amplifier

For static memories, the sense amplifier is often the standard one-stage CMOS differential amplifier with single-ended output, as shown in Fig. 5A. The function of the sense amp is in this case that of allowing for a quick reading of the differential signal on the bit lines, so that the discharging process can be stopped as soon as possible, to the advantage of speed and power consumption. One major drawback of this simple scheme is that the differential-pair M1, M2 operate in the triode region, as the bit lines are pre-charged to V_{DD} , leading to a severe degradation of the voltage gain.

A better solution is provided by a two-stage circuit scheme, where a differential level shifter, shown in Fig. 5B, is interposed between the bit lines and the voltage amplifier. The positive feedback of this circuit increases its differential voltage gain. Most important, the appropriate DC bias of the differential pair optimizes the amplifier gain, resulting in an excellent performance of the sense amp.

SRAM applications

In the past, when the available technology did not allow a huge number of transistors to be integrated on chip, stand-alone SRAMs were fabricated for the second level (L2) cache of Intel microprocessors.

Subsequently, device miniaturization made it possible to integrate L1, L2 and even L3 caches on chip as embedded memories, taking advantage from the SRAM compatibility with CMOS logic, with great performance and power consumption advantages at the system level. To date, cache memory is the dominant application of embedded six-transistor SRAMs for advanced microprocessors to be used in a wide variety of applications, from mobile to high performance servers. On the other hand, the market share of stand-alone SRAMs can be estimated to be less than 1% of the whole memory market.

In view of the above, the four-transistor memory cell with polycrystalline pull-up resistors or thin-film transistors has been practically abandoned due to the diminishing returns of its increased fabrication complexity, and to the difficulty to control the leakage current of pull-up resistors when the memory capacity becomes very large.

Dynamic random-access memory

Early DRAM cells were made by three transistors. The first proposal of a one-transistor, one capacitor (1T-1C) dynamic RAM cell was made by R.H. Dennard in 1966, who subsequently filed the US Patent no. 3,387,286 entitled "Field-Effect Transistor Memory," dated June 4, 1968 (Dennard, 1968). His basic idea was that cell information could be dynamically stored as a charge on a capacitor, as indicated in Fig. 6. Here again the MOSFET acts as a pass transistor, which can either isolate the cell or connect it to the bit line. The inner node voltage V_c may be set either at the supply voltage V_{DD} or at the ground voltage 0. In-order-to charge the cell capacitor

Fig. 5 SRAM sense amplifier; (A) Voltage amplifier; (B) Level shifter.

Fig. 6 One-transistor one-capacitor DRAM cell.

to V_{DD} , the word line must be driven to a higher supply voltage V_{PP} generated on chip. A disadvantage of this storage scheme is that, due to the transistor leakage current, the charge is not indefinitely conserved within the capacitor but, rather, leaks out in a time of the order of a several tens or a few hundred milliseconds. The limited DRAM retention time requires the information to be refreshed some tens or hundred times per second; hence, the definition of dynamic memory.

The cell capacitance must be as large as possible to ensure a long retention time as well as a safer reading of the stored information. At the same time, it must occupy a small silicon area, to allow for a large density and a small cost per bit. These conflicting requirements were pursued in the 1990s with either a trench or a stacked cell. In the former case, the capacitor was placed in a deep trench engraved within the silicon substrate by reactive ion-etching. The trench surface was thermally oxidized and filled with polycrystalline silicon electrically connected to the MOSFET source. This solution has been abandoned in recent years due to the extreme form factor required by the need to generate large capacitances with decreasing diameters values.

The stacked cell, shown in Fig. 7, aims to deploy a large capacitance (about 30 fF) by extending the surface of the upper electrode in an extended structure overlapping the word line (Koyanagi et al., 1978). This solution was subsequently improved by Taguchi et al. (1993) with a double-fin structure, usually made by electrically insulated polycrystalline silicon, and surrounded by the second electrode representing the capacitor plate. An added advantage of the stacked cell is that high- k dielectrics, such as ZrO_2 and/or Al_2O_3 , can be used as insulating layers, maximizing the total capacitance for a given occupation area.

Fig. 8 shows an electron micrograph of the stacked-capacitor cell (Taguchi et al., 1993). The double-fin structure, in light color as the silicide layer overlapping the transistor gate, represents the first electrode of the cell capacitor surrounded by a thin dielectric and a dark polysilicon plate. The transistor gate is connected to the word line by vertical W plugs shown in the upper part of the micrograph. The cell connection to the bit line is not shown in this cross section. More recently, the stacked cell has been

Fig. 7 Schematic view of a stacked DRAM cell.

Fig. 8 Electron micrographs of a stacked DRAM cell (Taguchi et al., 1993).

Fig. 9 DRAM capacitor structures. (Left) Pillar structure; (Right) Crown structure.

manufactured as a cylindrical pillar resembling a coaxial cable, or as a crown, as shown schematically in Fig. 9 (Left) and (Right), respectively. At the 25 nm technology node, the required capacitance value could be scaled to 17 fF, which can more easily be achieved with the crown structure comprising two capacitors connected in parallel.

On the other hand, the crown structure cannot be laterally reduced below a certain limit, thus preventing a full scaling of the cell. The pillar structure is thus used in advanced technologies, with an increased aspect ratio H/D about equal to 100 to achieve the required capacitance value at the 20 nm node. With such a capacitor structure, the DRAM cell can approach the minimum size of $4F^2$, with F the minimum feature size (half pitch) of the implementation technology. Fig. 10 is an electron micrograph showing a DRAM structure with vertical stacked capacitors (James, 2010).

DRAM cell array organization

The DRAM cell array may be organized as indicated in Fig. 11. The bit line is split in two identical segments connected to the sense amplifier, which allows for a differential reading of the stored information and halves the bit-line capacitance for a given column size. The bit-line folding makes it easier to match the layout of the sense amp onto the wider pitch of the two half columns and allows for an easy placement of the column decoders.

The bit lines are initially precharged at $V_{DD}/2$ by turning on transistor EQ and are then kept in a high impedance state. As for SRAMs, the row decoder addresses a row of cells and turns the corresponding pass transistors on, thus connecting the cell capacitors to their respective bit lines.

Fig. 10 Electron micrograph of a stacked-capacitor DRAM structure (Samsung 90-nm).

Fig. 11 Folded bit-line organization of the DRAM cell array.

Due to the large capacitance ratio between the parasitic bit line and the cell capacitances C_{bl} and C_c respectively, the bit-line voltage is only slightly affected. More specifically, the voltage change ΔV_{bl} of the bit line connected to the cell equals.

$$V_{bl} = [C_c / (C_{bl} + C_c)] (V_c - V_{DD}/2)$$

where V_c is the cell voltage, which may be either 0 or V_{DD} . If the ratio $C_c/C_{bl} \approx 0.1$ the voltage change ΔV_{bl} is only about one hundred mV. Due to an unavoidable offset of the sense amp, the cell capacitance must be as large as possible, while being dimensionally small to allow for a high bit density.

It is clear from the previous expression that the bit line voltage increases with respect to $V_{DD}/2$ if the cell voltage $V_c = V_{DD}$ and decreases if $V_c = 0$. The second input of the sense amp is connected to a reference voltage generated by a dummy cell precharged at $V_{DD}/2$, as the bit lines. Therefore, the properties of the sense amp must be the following: (i) It must detect and amplify a small voltage difference between the two bit lines, eventually generating logic levels; (ii) Upon reading, it must refresh the content of the cell by re-establishing the original value of the charge stored within the capacitor.

DRAM sense amplifier

The schematic of the DRAM sense amp is reported in Fig. 12 (Rabaey, 1996). Here M1-M4 form a regenerative, bi-stable circuit connected to ground via M5 and to V_{DD} via M6. An additional pass transistor M7 may either connect or isolate the two bit-lines, thus enabling their pre-charge at $V_{DD}/2$. Two dummy cells are located on the opposite sides of the sense amp and their capacitor is pre-charged at $V_{DD}/2$ by a straight connection to the bit lines. The function of the dummy cells is that of balancing the bit lines by letting them undergo the same transient conditions before readout.

At the start of a reading, SE is low, keeping M5 and M6 off; the bit lines are precharged at $V_{DD}/2$ and left in a high-impedance state. Thus, the cross-coupled transistors M1-M4 are self-biased on their respective thresholds, and the voltages V_3 and V_4 set at $V_{DD}/2 - V_{Tn}$ and $V_{DD}/2 + |V_{Tp}|$, respectively, V_{Tn} and V_{Tp} being the threshold voltages of the n- and p-channel MOSFETs, respectively.

The reading sequence is the following: (i) The word line of the addressed cell is activated, thus connecting its capacitor to the corresponding bit line, and so is the word line connected to the dummy cell on the opposite side of the addressed cell; (ii) SE is gradually raised high, allowing the sense amp to unbalance and reach its final state; (iii) The sense amps are read out via a column multiplexer; (iv) The word lines are reset to their low value; (v) The signal SE is switched low, thus turning off M5 and M6; (vi) The bit lines are shorted by raising the signal EQ, which drives them and the dummy-cell capacitors to $V_{DD}/2$; (vii) M7 is turned off by lowering EQ and leaving the bit lines in a high-impedance state. So doing, the initial reading conditions of the sense amp are reset.

It may be worth pointing out that, following the gradual raise of SE in step (ii), M5 and M6 turn on lowering V_3 and raising V_4 . The cross-coupled transistors M1-M4 turn on and unbalance the sense amp according to the initial voltage mismatch. If the initial bit-line voltage $V_{bl(left)} > V_{DD}/2$, which reflects the content of a logic "1" in the addressed cell, the transient drives it to V_{DD} while the right bit-line voltage $V_{bl(right)}$ goes to zero. The opposite situation occurs if $V_{bl(left)} < V_{DD}/2$, which reflects the content of a logic "0" within the same cell. Thus, reading the addressed cell restores the original voltage within the cell capacitor, which makes the reading non-destructive. Also, if the two bit-line capacitances are equal, pre-charge to $V_{DD}/2$ is simply achieved with no additional power consumption by connecting them via M7.

DRAM architecture

The block diagram of a DRAM bank is shown in Fig. 13. The block splitting in two parts is meant to reduce the bit-line capacitances. The row addresses are delivered to the row decoders, which activate one word line. All cells associated with that word line are thus connected to their respective bit lines, which become slightly unbalanced. The column addresses set the column decoder (actually, a simple multiplexer) and select the requested bytes or words, by connecting the corresponding bit lines to their respective sense

Fig. 12 Schematic of the DRAM sense amplifier.

Fig. 13 DRAM bank architecture.

amps. The logic levels generated by the sense amps are delivered to the output registers. Multiple column readings can be performed in sequence for any given row address, which improves the DRAM data rate. The above structure may be mirrored and replicated as many times as needed. The size of a DRAM bank is defined according to conflicting constraints: increasing the cell array size makes the layout more compact for a given DRAM capacity, but deteriorates the access time and, ultimately, the reading integrity, due to the larger word- and bit-line capacitances. In-order-to save package pins, a multiplexed addressing scheme, where the row and column addresses are presented in sequence to the same bus, is typically used. In this addressing scheme, two main control signals, namely, the row-address strobe (RAS) and the column address strobe (CAS) must be provided to the DRAM. Another control signal (WE) indicates if the intended operation is a read or a write.

Asynchronous DRAM

Basic DRAMs operate asynchronously under the control of external commands. The timing diagram of a read operation is shown in Fig. 14 (IBM, 1996), where the control signals RAS, CAS and WE are shown in complementary form, here denoted as RAS', CAS' and WE', respectively. The RAS' signal is switched low only after valid row address bits are present at the DRAM input buffer. In turn, the CAS' signal goes low only when valid column address bits and a valid WE signal are set to their respective values. The time t_{CAS} is the minimum time that CAS' must be kept low to generate valid output data; likewise, the time t_{RAS} is the minimum time that RAS' must be kept low to generate valid output data; finally, the cycle time t_{cycle} is the minimum time needed between two successive RAS' commands.

Improved asynchronous architectures, referred to as Fast Page Mode (FPM) and Extended Data Out (EDO) Mode, were developed since the early 1990s. An FPM DRAM makes it possible to access data located within the same row with a unique RAS command followed by multiple CAS signals, so long as all addressed words reside in the same row. Besides, the column address is latched, rather than being set up, at the falling edge of the CAS' signal. So doing, a reduced page cycle is obtained compared with conventional DRAMs (Veendrick, 2017).

The EDO DRAM differs from the FPM DRAM in that an additional register holds the output data. This makes it possible to start the next reading cycle before the previous one is completed. The cycle time is thus reduced, with some speed improvement over FPM DRAMs (Veendrick, 2017).

Fig. 14 Timing diagram of the DRAM input signals.

Synchronous DRAM

Synchronous DRAMs are driven by the system clock and are thus referred to as SDRAMs. Synchronous operation has several advantages: most notably, the possibility of a pipelined DRAM architecture with concurrent row and column addressing, and high-speed I/O operations. Taking advantage from the inherent parallelism of the memory core, this architecture improves the DRAM data rate, which is the most important performance parameter, while leaving its latency scarcely affected. Due to the hierarchical memory organization in modern computers, entire data blocks are in fact retrieved from the central memory when a block miss occurs at a higher level of the hierarchy. To date, the SDRAM data rate may be as large as 3.2 Gb/s/pin. This comes at the penalty of extra latches and buffers, as well as high-speed circuitry to support the I/O interface (Veendrick, 2017).

Basic SDRAM commands are chip select (CS), row address strobe (RAS), column address strobe (CAS), write enable (WE), data mask (DM) and data strobe (DQS). All of them are latched to the rising edge of the system clock. The CS signal is used to let the chip know that the incoming commands over the bus are intended for it. RAS, CAS and WE retain the usual meanings of row- and column-address strobe and write enable. DM masks the input data to unselected cells during a write; DQS is instead a bidirectional edge-aligned data strobe which toggles at the same time as the output data. This is made possible by a delay locked loop (DLL) which shifts the output data aligning DQ (I/O pins) and DQS. The bus width is most often 64-bit wide.

Basic SDRAM operations are activate (ACT), read (RD) or write (WR) followed by pre-charge. SDRAM operation can be configured for CAS latency and burst length by setting the 12 bits of the load mode register (LMR). The burst length determines the amount of data transferred in consecutive cycles between the memory controller and the memory after applying one start address. The typical delay between the RAS and CAS signals is two clock cycles, and the CAS latency is again two clock cycles; thus, the access time is four clock cycles. The SDRAM cycle time t_{cycle} depends in this case on the bus width and the burst length (Veendrick, 2017).

Several generations of SDRAMs were successively offered to the market: Double Data Rate (DDR) 1, 2, 3 and 4, with progressively decreased supply voltages and improved data rate. The key concept of DDR SDRAMs is that both the falling and rising edge of the clock are used to double the data throughput. DDR2 operates at 400–800 MHz bus rates with a supply voltage $V_{DD} = 1.8$ V. DDR3 operates with bus rates of 800–1600 MHz at $V_{DD} = 1.5$ V. The doubling of the bus rate in DDR3 is achieved by prefetching 8 rather than 4 words. So doing, a total of 8 words are accessed in parallel for a read or write operation. In DDR4, the connection between CPU and Memory is not done using a bus but, rather, point-to-point direct channels. This simplified connection puts an additional burden on the memory controller, which must operate reliably at very high frequency maintaining the signal integrity. To do this, impedance matching is required to prevent signal reflections (Veendrick, 2017).

Rambus DRAM

The direct Rambus DRAM (RDRAM) architecture is based on a system approach, which maximizes the data rate on the memory board by carefully synchronizing data, addresses and commands with the clock signal (Crisp, 1997). The key elements of this technology are the following: (i) a 16-bit wide, 800 MHz channel; (ii) an on-board interface that lets the memory controller talk to the RDRAM and, (iii) an in-line memory module called RIMM.

Fig. 15 Direct Rambus DRAM architecture.

A Rambus channel includes a controller and a variable number of RDRAM chips connected via a linear common bus. As shown in Fig. 15, the controller is located at one end, and the RDRAMs are distributed along the bus, which is terminated at the opposite end with the characteristic impedance of the lines connected to the high-voltage level. Therefore, the bus driver operates in the open-drain configuration. The 400 MHz clock signal is generated at this same end; it propagates along a bus line connecting the clock generator to the controller and turns back to the terminating end of the bus line. All commands, addresses and data moving from the controller to the RDRAM chips and back are synchronized on the edges of the clock which propagates in the same direction. So doing, clock skew is minimized.

The channel uses 18 data pins, two of which for error correction code (ECC), cycling at 800 Mb/s per pin to provide a bandwidth of 1600 MB/s. This is achieved by latching data on both the rising and the falling edges of the clock signal. The RDRAM has a pipelined micro-architecture, which fully supports concurrent RAS and CAS operation, as well as read/write buffering. Also, it provides 16 bytes every 10 ns on the internal bus. The Rambus interface transforms the 10 ns internal bus into an external, two-byte wide, 1.25 ns external bus.

All signal wires have an equal loading and fan-out and are routed parallel to each other on the top trace of a PCB with a ground plane located underneath. The addition of more RDRAM chips linearly increases the load and the delay, but leaves the phase relationships of the clock, data, addresses and commands unaltered. Also, the memory granularity is simply given by the memory capacity of one chip.

Graphics applications

Graphics applications require extremely high bandwidths, being characterized by high speed and wide I/O buses. Video RAMs (VRAM) and Synchronous Graphics RAMs (SGRAM) are specifically designed for such applications and are widely used in graphical signal processors (GSP) for PC video cards. Most VRAMs are a dual-ported version of a DRAM, meaning that the display is reading its image from the video RAM, while the processor is writing a new image into it. One access port is used to constantly refresh the display and the other is used to change the data to be displayed in the next frame. A bandwidth doubling and faster video performance is thus obtained, with reduced CPU strain. The VRAM acts as a buffer between the processor and the display monitor and is often called frame buffer.

SGRAM architectures are similar to SDRAM's, while being optimized for color graphics applications. More specifically, SGRAMs support block write and write-per-bit functions. These features are made possible by special registers used to store the color data associated with large areas of a single color. Write per-bit allows the masking of certain inputs during write operations; hence, only some memory locations are written rather than the whole frame, resulting in faster and more efficient read and write operations (Veendrick, 2017).

Capacitorless DRAM cell

Several capacitorless DRAM cells have been proposed, which take advantage from the floating body effect of silicon-on-insulator (SOI) technology (Yoshida and Tanaka, 2006; Okhonin et al., 2008). Besides reducing the cell area and fabrication complexity due to the elimination of the stacked capacitor, the added advantage is the full compatibility with the SOI CMOS process, which makes these memories suitable for embedded implementations in systems-on-chip.

The information is typically stored as a hole charge within the isolated body of a partially depleted (PD) SOI transistor, which lowers its threshold voltage and makes it more conductive, as shown in Fig. 16. The hole charge is inserted into the transistor body either by Impact Ionization (II) at large drain voltages or by a negative gate voltage pulse which enables Gate-Induced Drain Leakage (GIDL) under positive drain voltage. The latter approach is preferable from the standpoint of power consumption. Electrons from the body valence band tunnel into the positively biased drain, leaving behind several holes within the transistor body. This corresponds to the write 1 command. Holes can be removed from the transistor body by a drain negative pulse, which makes the body-drain junction forward biased. Holes are thus injected into the drain, so that the transistor body becomes fully depleted, and the threshold voltage is raised. This represents the write 0 command. The Read operation can simply be carried out by sensing the source current at low drain bias (typically 0.2 V).

Fig. 16 Schematic of a capacitorless DRAM cell.

Retention times are shown to be acceptable under standby conditions ($V_{GS} = -1$ V, $V_{DS} = 0$ V), despite the small capacitance value of the floating body. As opposed to standard DRAM cells, however, a write disturb can affect the 0 content of unselected cells connected to the addressed word line, when a large negative pulse is applied to it for a write 1 operation. Likewise, a write 0 command using a negative drain pulse can affect the unselected cells connected to the addressed bit line.

Readout is carried out at small drain voltages and is non-destructive but, at the same time, does not refresh the cell content. Therefore, memory refresh does not occur automatically by starting a read cycle word line after word line, as for standard DRAMs, but requires the cell content to be read and rewritten location after location. Capacitorless DRAMs are compatible with the SOI technology and can be easily integrated in systems on chip fabricated in that technology. For the time being, only embedded memories with limited capacities have been produced.

General considerations on volatile memories

Stand-alone SRAMs exhibit a performance advantage over DRAMs by a factor of about 4, partially due to different design goals of the two memory types. The former memories are in fact designed with the aim to optimize performance, while the latter ones are designed for high density and, thus, low cost per bit. As a result, the sizes of SRAM and DRAM cells are about $100\text{--}150$ F² and $4\text{--}6$ F², respectively. Multiplexing the row and column addresses to reduce the pin number, and the consequential need to assert the RAS and CAS signals in sequence, shows that the cycle time was sacrificed to the cost target.

On the other hand, DRAM designers managed to improve the data rate by accessing a full page without requiring a new reading cycle to start. A page is given by all cells sharing the same word line and can be as large as one or more kilobit. The simultaneous readout of a full page makes the data rate as large as one or more Gbit/s in the most advanced page-mode designs. Therefore, the market share of standalone memories is dominated by DRAMs, while SRAMs cover only about 1% of the whole memory market.

DRAM chips only use 2–4 metal layers, as opposed to the 10 metal layers of advanced microprocessors. Besides, the stacked capacitor cell requires additional processing steps which are not compatible with the state-of-the-art CMOS technology. A consequence of such a specialized DRAM technology is that embedded DRAMs in systems on chip require a much larger planar capacitor, which increases the cell size by a factor of 6 to 8. The area efficiency of stand-alone DRAMs is thus largely lost in embedded applications. Nevertheless, embedded DRAMs have been used for high-performance systems-on-chip requiring a relatively small memory capacity, such as graphics and multimedia applications (Yamazaki, et al., 1999).

Embedded memories for high performance applications, such as cache memories, are predominantly SRAMs. Fig. 17 shows Intel's Nehalem microarchitecture chip comprising four i7 cores. It appears that the shared L3 SRAM area occupation is about one third of the whole chip, while the four L2 SRAMs are recognizable as the regular layout areas in the lower right or left sides of every core processor (Thomadakis, 2011).

Fig. 17 Intel's Nehalem architecture comprising four i7 cores and a large shared L3 cache.

Content-addressable memory

Modern computer architectures rely on a hierarchy of memories comprising three levels of cache in addition to the central memory. This complex organization is due to the design consideration that smaller memories are faster, and to the locality principle, according to which programs tend to reuse either data which have already been used in previous cycles (temporal locality) or data sets stored next to the used data (spatial locality).

At the first level of the hierarchy, we typically find an instruction and a data cache with a typical capacity of 16–64 KB, and a data rate of one instruction/data per cycle if a hit occurs. The second-level caches are larger, around a few MB, and relatively slower. Third-level caches are typically shared by the on-chip cores and their capacity may be several hundred MB. The area occupation of the third level cache is a very substantial fraction of the whole microprocessor chip.

Cache memories are classified according to the criteria by which the central memory is mapped onto it. In a fully associative cache, data blocks can be stored anywhere within the cache, as opposed to direct-mapped memories, where the block address uniquely defines its location. In most cases, cache memories are n -way set associative; this means that the cache memory is split in several sets each containing n blocks: the block address uniquely defines the set where it must be stored, but the location of the block inside the set (way) is free.

In any case, a tag memory containing a list of the block addresses stored within the cache is needed. When a new instruction or a new data is requested by the processor, an associative search must be performed on the tag memory to find out if the block containing that instruction or data is stored within the cache and, in case it is, in what location. As opposed to standard memories, the input of the tag memory is a data word, and its output is the local block address within the cache. The tag memory is therefore a content addressable memory (CAM). The basic cell of a CAM, shown in Fig. 18, contains 10 transistors.

The information bit is stored within a static latch made by the two cross-coupled inverters I1 and I2. Two pass transistors M1 and M2, driven by the write line (WL), connect the input data D and its complement D' to the latch outputs, thus writing the input bit to be stored. As shown in the figure, two couples of pass transistors M3–M4, M5–M6, driven by the input data D and D' and by the latch outputs connect to ground a pre-charged match line (ML). If the stored bit is opposite to the input data, either one of the two couples of pass transistors is on discharging the match line. Otherwise, the match line remains biased at V_{DD} . The former case indicates that no match occurs between the input and the stored data; the latter indicates the opposite condition.

The above cells are organized within an array, and all the cells of a column, sharing the same write line and the same match line, contain the address of one memory block. If any one of the above cells does not match its input bit, it drives the match line to ground, indicating that no match occurs between the input word and the stored address. If none of the columns matches the input word, this means that a block miss is occurring; all the match lines are at ground potential and a NOR gate rises the block-miss signal high. If, on the other hand, all input bits of a column match their respective bits stored within the cells, the match line remains high. This is an indication that the requested block is stored within the cache, and the high match line indicates the internal address of the block within the cache memory. In this case a hit signal is released.

Fig. 18 The 10-transistor CAM cell.

Conclusion

In this Encyclopedia entry, volatile random-access memories are presented, with special attention to static and dynamic RAMs. Cell topologies, array organizations, reading and writing procedures, reliability issues and typical applications are illustrated. Their performance properties, including access time, data rate, area efficiency and power consumption are discussed with some detail, specifying the different application-specific architectures. Content addressable memories are also treated in the final part of this entry.

The stand-alone memory market is and will be dominated by DRAMs in the foreseeable future, due to their area efficiency, unlimited endurance, low cost per bit and high data rate, which has grown to fulfil the requirements of high-performance processors, despite the relatively large DRAM access time compared with the cycle time of the internal clock. To compensate this mismatch, every access to the central memory is going to transfer a full page, both for writing and for reading after a block miss of the L3 cache.

As far as embedded memories are concerned, SRAMs are the typical high-performance solution. For less demanding and lower cost applications, different kinds of memories are being used. Due to the limited DRAM suitability, these memories are in most cases non-volatile and compatible with logic technologies with a small additional number of processing steps in the back end of the chip fabrication. Among them, phase-change memories, to be discussed in the next entry of this memory presentation, are often used for systems on chip.

As the supply voltage of advanced microprocessors was scaled down to 0.7 V, however, SRAMs turned out to be affected by two major weaknesses: (i) an increased leakage current, due to threshold voltage scaling and, (ii) a deterioration of the noise margins, which led to more complex cell architectures with additional devices and/or to the use of external assist circuits. The former point is detrimental to power consumption, which must be contained due to the limited heat extraction capability from chips and to the need to save power in mobile applications. The latter point affects the SRAM read reliability and its solution leads to an increased chip size and fabrication cost.

The advent of the FinFET (tri-gate) device architecture for logic at the 22 nm technology node and below, has added additional constraints to the SRAM design, due to the fixed FET effective width $W_{\text{eff}} = 2H + W$, with H the fin height and W its physical width at the top, uniquely defined by the fabrication technology. High-performance SRAMs use one single Fin-FET for the pull-up devices M2 and M4 (see Fig. 2), two parallel FinFETs for each of the pass transistors M5 and M6 and two or three parallel FinFETs for the pull-down devices M1 and M3. These constraints are detrimental to the cell size, which can become as large as $150 F^2$.

According to a recent study, Spin Transfer Torque (STT) magnetic RAMs could possibly replace SRAMs as the last level cache (LLC) in microprocessors at the 5 nm technology node (Sakhare et al., 2020). This could be a major technology shift, as the number of transistors in LLCs is a large fraction of their total number, which amounts to a few billion.

Abstract

Residual stresses and strains are introduced through *nuclei of strain* (elastostatics 'charges') and, in the case of continuous distributions, *eigenstrains* ('frozen-in' permanent inelastic strains). The problem of eigenstrain is introduced using a form of the complementary energy functional for the problem of elastostatics in the presence of eigenstrain. The direct and inverse problems of eigenstrain are introduced then, and the approaches to solving them are presented. The means of experimental evaluation of stress and strain are critically reviewed. The challenge of 3D reconstruction of a sample's internal residual deformation state is considered in the context of stress/strain tomography. Residual stress and strain effects on structural integrity are briefly reviewed.

Key points

- To introduce the concept of residual stresses and strains in complex hierarchically structured materials
- To identify eigenstrain as the source of residual stress
- To introduce eigenstrain theory of residual stresses along with the direct and inverse problems of eigenstrain
- To introduce the continuum mechanical theoretical (variational) framework for residual stress analysis
- To introduce the statistical and multi-scale nature of residually stressed and strained states
- To introduce key experimental approaches to residual stress evaluation
- To discuss the Focused Ion Beam – Digital Image Correlation (FIB-DIC) technique
- To introduce synchrotron X-ray diffraction methods for residual stress analysis
- To introduce the concept of 3D strain analysis by diffraction strain tomography

Introduction

Residual stresses represent internal forces that persist inside solid objects upon the removal of all external mechanical loads and constraints. The very nature of this definition implies the presence of some internal source(s) of residual deformation that gives rise to residual stresses. To identify these sources, it is instructive to consider the additivity of strain expressed by the simple formula

$$\varepsilon^{tot} = \varepsilon + \varepsilon^* \quad (1)$$

Here the total strain is additively decomposed into elastic strain denoted ε and inelastic part denoted ε^* that is often termed *eigenstrain* in the literature (Mura, 1982; Korsunsky, 2017). *Eigenstrain* represents *material memory* of inelastic deformation that may be induced by plastic flow, phase transformation, spatially inhomogeneous thermal expansion, and imaginary cutting and gluing exercises (Hills et al., 1996). The total strain ε^{tot} must satisfy Saint-Venant's compatibility equations to preserve material continuity, while the elastic strain via the generalized Hooke's law is linked to the stresses that must satisfy equilibrium conditions.

Eigenstrain theory

The problem of residual stress determination from a known *eigenstrain* distribution – the *direct problem of eigenstrain* (Korsunsky, 2017) – is simple and can be readily solved using analytical or numerical approaches, e.g., by imposing *eigenstrain* as pseudo-thermal strain distributed within the volume of consideration. Examples of *eigenstrain* acting as a source of residual stress can be drawn from the solutions in the theory of elasticity (Love, 1944; Eshelby, 1957). Further examples of nuclei of strain (term used by Mindlin and Cheng, 1950) can be derived for more complex situations e.g., related to problems in the theory of fracture (Korsunsky, 2017, 1995; Hills et al., 1996).

In most practically relevant problems, however, the underlying distribution of eigenstrain that gives rise to the residual stress distribution is unknown. This gives rise to the *inverse problem of eigenstrain*, namely, its determination from partially evaluated distribution of residual stress, residual elastic strain (also referred to as r.e.s.) denoting the elastic strain e that is present within an unloaded solid object complying simultaneously with the compatibility and equilibrium equations. The inverse problem of *eigenstrain* is a hard problem in the sense that it is implicit and can be ill-posed in terms of non-uniqueness of solution and limited extent of input data for *eigenstrain* reconstruction.

A number of methodologies have been proposed for the solution of the inverse problem of *eigenstrain*. The most straightforward approach involves the representation of *eigenstrain* distribution as a weighted sum of basis functions that may be globally defined on the entire domain of consideration or locally, e.g., in the form of element-based or radial basis functions related to specific locations within the sample. Using this representation, the residual stresses can be obtained as a linear sum of basis solutions of the direct problem of *eigenstrain* with the same weights. Optimal matching of the linear sum representation to the observations e.g., by minimizing the sum of squared mismatch values with respect to the unknown coefficients via non-iterative inversion of the linear system of equations (Korsunsky, 2017). Further refinement of the approach can be derived using variational calculus, e.g., using the complementary energy functional in the form (Wang et al., 2022):

$$\Pi(\sigma_{ij}, e_{ij}^*) = \int_V B(\sigma_{ij}) dV - \int_{S_u} \sigma_{ij} n_j \bar{u}_i dS + \int_V \sigma_{ij} e_{ij}^* dV. \quad (2)$$

Here the boundary displacement $\bar{u}_i$ is known on the part of the boundary S_u of the material volume V , and $B(\sigma_{ij})$ is the complementary energy defined by its relation to the elastic strain e_{ij}^e ,

$$\frac{dB(\sigma_{ij})}{d\sigma_{ij}} = e_{ij}^e. \quad (3)$$

Thus, if the inelastic strain (eigenstrain) e_{ij}^* is known throughout the body, then the residual stress distribution σ_{ij} is found to deliver a stationary value to the variation of the above functional $\delta\Pi$, thus providing the solution to the *direct problem of eigenstrain*. If the eigenstrain e_{ij}^* is unknown, the above formulation can be modified to account for a region of known stress, and the eigenstrain determined, providing the solution to the *inverse problem of eigenstrain*.

A key aspect of residual stress state is that the distributions must be self-equilibrating in terms of force and moment balance. Importantly, this requirement applies not only to the entire volume of the object being considered, but also to any subset of it that can be obtained by real or imaginary sectioning. Sub-volumes of material must experience self-equilibrating surface tractions that are found at its surfaces during imaginary sectioning. This thought experiment immediately leads to the realization that residual stresses possess hierarchical nature and can be thought of at different scales depending on the choice of imaginary section dimensions.

Stress and strain multi-scaling

To aid the appreciation of the hierarchy of internal stresses, classifications related to scale have been introduced (Davidenkov, 1950; Hauk, 1997). This is concisely expressed in the additive scale-related decomposition that can be applied to both stresses and strains:

$$\sigma = \sigma^I + \sigma^{II} + \sigma^{III}, \quad \varepsilon = \varepsilon^I + \varepsilon^{II} + \varepsilon^{III}. \quad (4)$$

Type I stresses and strains are associated with the overall geometry of an engineering component or sample, typically varying smoothly on the scales from millimeters to meters and greater. A key aspect of Type I stresses (and strains) is the assumption that material can be thought of as continuum with uniform or slowly varying properties. In contrast, Type II stresses and strains manifest themselves at the scale of typical microstructural elements of metallic and ceramic polycrystals, i.e., grains that possess distinct lattice orientation and associated orientation-dependent elastic and plastic properties (anisotropy). Type II stress and strain components represent grain-average deviation (addition) to Type I macroscopic continuum base line (Fig. 1B). Type III stresses and strains represent the additional deviation from Type I+II values associated with intragranular crystal lattice defects that can be discerned on the scale from hundreds down to single nanometers. A rational physical explanation for the emergence of these distinct scales has been proposed (Korsunsky and Salimon, 2018) in relation to the prevalence of distinct sets of equations of mathematical physics at each recognizable scale that determine the deformation behavior and its suitable description.

Fig. 1 (A) The microstructure of a metallic alloy representative volume element (RVE), with (B) superimposed line profile of a residual stress component variation obtained by crystal plasticity finite element modelling (CPFEM). Reproduced with permission from Chen JW, Wang Z, and Korsunsky AM (2022) Multiscale stress and strain statistics in the deformation of polycrystalline alloys. *International Journal of Plasticity* 152: 103260.

Statistical considerations

It is further possible to consider the problem of internal stresses and strains within the framework of multi-scale statistics description. To aid discussion, we borrow the illustration in Fig. 1 from (Chen et al., 2022) that shows a line profile of a particular component of (residual) stress obtained from crystal plasticity finite element model (CPFEM) that has received extensive validation against experimental methods of residual stress evaluation (discussed later here). Viewed at the finest (nanometric) scale of discretization and evaluation, the line profile of residual stress represents a one-dimensional signal that contains high and low frequency components. The application of a low pass filter to this profile returns a representation of the stress variation that is smoothed to a chosen extent (length scale) that can be chosen e.g., to obtain Type I contribution. The application of an intermediate pass filter similarly returns Type I+II sum, so that Type II stress profile can be obtained as the difference. Finally, the subtraction of the Type I+II sum from the original distribution returns Type III contribution.

The above discussion paves the way to further spectral analysis of stress contributions at different length scales as a function of the spatial period of variation. To illustrate the idea, the left panel in Fig. 2 shows a line profile of a stress component along with the right panel containing an annotated *periodogram*, i.e., a power spectral density plot. For convenience of analysis, the RVE was chosen to extend from -0.5 to 0.5 consistently with the accepted convention in spectral signal analysis. Since the modelling approach used in the CPFE simulation of Fig. 1 did not contain explicit description of intragranular defects (strain nuclei), the profile was enhanced with random variation at this scale, as can be seen in Fig. 2A. Spectral analysis illustrated in Fig. 2B allows three ranges to be identified. Namely, at length scales exceeding 0.25 units (approximately twice the linear grain size) the periodogram appears appreciably flat and corresponds to Type I residual stress variation at the longer (super-granular) length scale. The range between 0.1 and 0.25 units shows a transition that covers the intermediate scale that corresponds to Type II (inter-granular) length scale. Finally, in the range below 0.1 units the periodogram shows further increase in magnitude toward the maximum observed for the smallest dimensions and corresponds to the Type III (intra-granular) length scale.

The approach outlined in the paragraph above sets the basis for a range of further possible generalizations. For example, the highly successful Krylov-Bogolyubov method of approximations for oscillating mechanical systems has not been applied, to the best of our knowledge, to two- or three-dimensional distributions of strains and stresses in deformable solids. To a large extent this can be explained by the experiment impediments to obtaining sufficiently reliable and detailed 2D and 3D maps of these complex multi-component quantities, in contrast with the ready availability of 1D signal data. However, in recent decades significant advances were made using experimental techniques based on strain relief (mechanical milling and sectioning) and high-resolution strain mapping that employ focused X-ray and electron beams.

'Live' vs residual strains and stresses

Before embarking on the more in-depth discussion of experimental techniques for strain measurement and stress evaluation, it is important to establish a distinction between strains that are observed to evolve 'live' from initial to current state, on the one hand,

Fig. 2 (A) Line profile from Fig. 1B modified to introduce short range stresses reflecting intragranular variation, and (B) “periodogram” of the distribution with the Type I, II and III ranges indicated.

and strains that persist within an object or sample as a consequence of processing that was not or could not be observed; in other words, when a ‘reference state’ is not known.

The concepts of ‘reference state’ and ‘current state’ are generally important and worth dwelling on here. In traditional continuum solid mechanics, as the material is considered to be homogeneous and structure-free, it is natural to assume that the reference state corresponds to the situation when there is neither elastic nor inelastic strain present in it, and all subsequent deformation can be measured in relation to that state. In many cases when small deformations are considered, it is convenient and suitable to use Lagrangian description that follows individual material ‘particles’.¹ Tracking the field of displacements of these particles throughout the deformation from the reference to the current state furnishes complete information sufficient to compute the strain field. This task is most conveniently accomplished using Digital Image Correlation (DIC) (Paine, 1986) for 2D mapping of surfaces (or 2D projections for non-flat samples), or Digital Volume Correlation (DVC) (Baimpas et al., 2012) for 3D mapping when non-destructive volumetric imaging can be obtained using X-ray, optical, or other tomography techniques. A noteworthy demonstration of 2D mapping of 3D displacements at sample surface using height-sensitive Digital Image Correlation (hDIC) employing image stacking optical microscopy is presented in Uzun and Korsunsky (2019). Numerous examples can also be found in the literature illustrating DVC deformation mapping in 3D (Baimpas et al., 2012).

Digital image correlation (DIC)

DIC and/or DVC mapping of displacements thus provides a general solution to the problem of ‘live’ strain evaluation. It can be accomplished using digital imaging techniques at any resolution sought (subject to resolution attainability). Note that the total strain field thus obtained does not provide decomposition into elastic and inelastic parts according to Eq. (1). Since the former is required to evaluate the stress field, there remains the need to employ some means of separating the elastic strain.

Further challenges arise when the reference state cannot be registered prior to deformation, precluding the possibility of displacement tracking. Indirect approaches have been proposed that monitor some aspect of material physical response to external excitation to deduce the local residual stress state via its coupling to, e.g., magnetic permeability, birefringence, spectroscopic signature (Raman), hardness, etc. While these techniques provide useful guidance, they are often qualitative, sensitive to hydrostatic stress rather than specific components, and restrictive in terms of materials classes (ferromagnetic steels, transparent polymers), and will not be considered further here.

A general quantitative approach to residual stress evaluation involves minimally disturbing material removal associated with the creation of new surfaces and unloading (reduction of tractions), sometimes incorrectly referred to as ‘strain relaxation’ – this implies inelastic deformation, whereas in fact the assumption is made of only elastic *strain relief* taking place. As a consequence, at least some material volumes undergo partial or complete unloading back toward the strain-free reference state, allowing the current state to be reconstructed via numerical analysis.

The following sections are devoted to the techniques for quantitative experimental evaluation of residual strain and stress tensors. These form two principal classes, namely, the partially destructive material removal and strain relief methods, and the diffraction methods.

¹It is worth noting that this principle, however, requires the installation (or, at least, identification) of embedded ‘markers’ and thus contradicts the assumption of featureless continuum.

Experimental techniques

The experimental evaluation of residual stress must be understood precisely. In practice, it is not possible to *measure* stress because of its definition as internal force component acting on a chosen imaginary cross-sectional area. At best, the force may be assessed, but in practice most of the time it is the deformation parameters (displacements and strains) that are measured, while stress is deduced. This is aided by the universality of the Hooke's law that can be understood to act both ways: stress is expressed as the sum of products of material stiffnesses by the corresponding components of elastic strain; and conversely, elastic strains can be thought as those obtained from partitioning in Eq. (1) that are related to the stresses via Hooke's law. Thus, the determination of elastic strains is tantamount to indirect stress evaluation because of the necessary further step of Hooke's law application that carries unavoidable additional uncertainties.

As noted above, a particular difficulty in residual stress evaluation through elastic strain measurement is that the reference state is no longer accessible by the time the sample is provided – otherwise it would be possible to trace the evolution of elastic strains throughout the processes that led to the residually stressed current state. However, such is the complexity of such processes as casting, rolling, hot forging, machining etc. that are known to give rise to residual stresses that it is practically not possible to equip the object with spatially distributed markers for strain monitoring. Furthermore, in all of these processes strain arises as a combination of elastic and inelastic parts, presenting the additional challenge of their separation according to Eq. (1) for the purpose of stress evaluation.

The paradigm of residual stress evaluation illustrated in Fig. 3 is based on material removal (severing the material connections that transmit internal stress) accompanied by monitoring and quantifying the induced strain relief (Lunt and Korsunsky, 2015). These examples are drawn from microscopic studies (note the scale bars) but represent the geometries commonly used at the macro-scale, also illustrating the scalability of this class of approaches. The two crucial aspects here concern the availability of the means of precise minimally disturbing milling and strain evaluation at the appropriate resolution. In the case of macroscopic analysis, high speed milling, drilling and electric discharge machining are used in combination with strain gages, touch probe or optical profilometry (Schajer, 1992; Prime, 2001). At the micro- to nano-scales, experiments are performed within the vacuum chamber of a Focused Ion Beam – Scanning Electron Microscope (FIB-SEM) instrument, with ion particles used for material removal and electrons for surface imaging.

Material removal method illustration: FIB-DIC

We dwell here in particular on the discussion of the micro-ring-core FIB-SEM method (Fig. 3C) (Korsunsky et al., 2008) that provides a convenient illustration of the key aspects of material removal and relief methods. In this method, the severing of the

Fig. 3 A gallery of material removal and strain relief geometries: (A) Slitting, (B) Blind hole drilling, (C) Ring-core milling, (D) H-bar geometry. connections between the central micropillar and the surrounding material leads to progressive unloading from the prior residual stress as the cut deepens. When the circular 'trench' depth becomes equal to the central pillar diameter, surface relief becomes complete (Salvati et al., 2019). The method thus represents the embodiment of the principle of strain relief back to the reference state. The strain change that is registered at the micropillar top surface due to milling represents the opposite of the local residual elastic strain that was present in the residually stressed sample. In accordance with the aforementioned scale-dependent definition of strain and stress, the micropillar diameter sets the scale for averaging, so that a single value of each strain and stress component should be assigned to the entire volume to avoid ambiguity. The smallest reported diametral dimension of the micro-pillar used in the FIB-DIC micro-ring-core method was smaller than one micron (Salvati et al., 2019). It should be known that the macroscopic equivalent known as the ring-core method has been known since 1950s and more recently described in detail by Keil (1992).

Exhaustive reviews of the experimental procedure and data analysis and interpretation for the FIB-DIC micro-ring-core method were provided by Lunt (Lunt and Korsunsky, 2015). Salvati et al. (2016a, b) considered the effects of material elastic anisotropy on the strain relief and incorporated this in the procedure for residual stress evaluation. This important advance opens up the path toward probing local grain scale effects in metallic and ceramic materials with clearly defined crystalline grains of specific orientation that can be determined, e.g., using back-scattered electron diffraction (EBSD).

Depth profiling of residual stress using the FIB-DIC micro-ring-core method has pushed the limit of the spatial resolution toward the nano-scale, with the smallest reported resolution step being as small as 50 nm (Salvati et al., 2019). This has been accomplished using multiple core diameters and employing eigenstrain-based analysis.

The micro-scale nature of the FIB-DIC micro-ring-core method allowed performing studies that reveal the multi-scale and statistical nature of residual stress states in polycrystalline materials. Everaerts et al. (2018) carried out the evaluation of residual stress in a laser shock peened sample with the average grain size of 6 μm . Fig. 4 illustrates the alloy microstructure (Fig. 4A) along with FIB-DIC data obtained using 5 μm and 10 μm diameter micro-ring-core milling (Fig. 4B). Fig. 4C shows the comparison with the measurements carried out about a decade earlier using an alternative technique of synchrotron X-ray diffraction (see discussion below). There is a significant disagreement (Fig. 4B) between the two sets of results that could be incorrectly attributed to residual stress modification (relaxation). However, once the core diameter was increased to 10 μm , much better match is obtained between these independent methods. The difference between the results obtained from FIB-DIC micro-ring-core must be attributed to the

Fig. 4 (A) EBSD map of Ti-6Al-4V alloy bar. (B) Results of FIB-DIC evaluation of residual stress using ring-core diameters of 5 μm and 10 μm . (C) Comparison of 10 μm ring-core FIB-DIC results with synchrotron XRD profiling of residual stress. Reproduced with permission from Everaerts J, Song X, Nagarajan B, Korsunsky AM (2018) Evaluation of macro- and microscopic residual stresses in laser shock-peened titanium alloy by FIB-DIC ring-core milling with different core diameters. *Surface and Coating Technology* 349: 719–724.

scale dependence of residual stress: 5 μm diameter core measurements contain information about both Type I and Type II contributions to the residual stress, while 10 μm appears to provide sufficient averaging similar to that achieved using large scattering volume used in the synchrotron X-ray experiment (Korsunsky et al., 2006a) to reveal pure Type I stress contribution.

The results obtained in this study motivated a further investigation (Salvati and Korsunsky, 2017) aimed at revealing the statistical multi-scale nature of residual stress states within metallic polycrystals. An aluminum alloy polycrystal sample in a form of bar was subjected to plastic bending to create a controlled distribution of residual stresses of Type I, II and III. The macroscopic stress-strain curve of the material was collected and used to calibrate the continuum description of the plastic flow that was incorporated into a finite element model of the bending process. The model was validated through comparison with the observation of sample bending and matching the residual bending curvature. In addition, crystal plasticity finite element modelling (CP-FEM) was carried out that provided numerical prediction of local residual stresses (Type I + II). FIB-SEM evaluation of residual stress was carried out to obtain experimental values of Type I + II + III stresses.

Comparison between the modelling and experimental data obtained demonstrated that the microscopic (Type II + III) residual stresses possess significant statistical variation that obeys a Gaussian distribution with the width that is comparable in magnitude with the local Type I stress value. It is important to note that this statistical variation represents the physical nature of the complex internal stress state within the material and should not be confused with random measurement error or scatter.

Diffraction

Crystalline materials are distinguished by the presence of a regular internal lattice composed of repeated pattern (unit cell) that fills the space in a repeated manner and is characterized by a long-range order with specific dimensional periods depending on the chosen direction. The fact that lattice periods for metallic and ceramic materials typically lie in the range 1-10 $\text{\AA}$ was discovered by Laue and co-workers when they successfully conducted first polychromatic X-ray diffraction experiments to reveal crystal symmetries and formulated the relationship between the radiation wavelength, interplanar lattice spacings and scattering angles. This was subsequently expressed by Braggs in the form of the simple equation

$$2d \sin \theta = \lambda, \quad (5)$$

where θ is half of the scattering angle 2θ . The above expression signifies that the interaction of material with any penetrating radiation of a suitable wavelength provides a means of precise measurement of lattice spacing and its change. For example, if monochromatic radiation with a precisely set wavelength is used, then the following relationship between lattice spacing change δd and angle change $d\theta$ can be obtained:

$$\delta d \sin \theta + d \cos \theta d\theta = 0. \quad (6)$$

If the lattice parameter change is induced by elastic strain, then it can be expressed from the above equation as

$$\epsilon^{el} = \frac{\delta d}{d} = -\cot \theta d\theta. \quad (7)$$

The application of Bragg's law to the problems in the mechanics of materials provides a means of elastic strain evaluation by monitoring the variation of scattering angle 2θ as a function of applied or residual stress. Beams of electrons or X-rays commonly employed for this purpose are often monochromated to fix the radiation wavelength and collimated to define the interaction volume within which the measurement is performed.

The advantage of the above method is that it does not require the introduction of markers nor material milling, and thus can be classed as truly non-destructive. Furthermore, inelastic deformation such as crystal slip is associated with lattice plane gliding and not dilatation (change of spacing), so diffraction provides a means of separating the total strain into the elastic (measured) part and inelastic part. Due to the geometrically precise nature of beam-materials interaction, the strain component (direction) determined in this way is precisely defined, allowing in principle the complete elastic strain tensor to be determined. As specific lattice reflections are employed, the method also allows distinguishing between different crystallographic and thermodynamic phases.

A major challenge in applying the diffraction method to residual elastic strain determination is the need for the reference state information, namely, the unstrained lattice parameter value d to be used in Eq. (7). This requirement is often dealt with by grinding the material into fine powder effectively making use of the approach mentioned above: relieving surface tractions on small particles to allow their internal stresses to reduce to zero. Scattering from untextured powders provide azimuthally symmetric scattering of incident beam into a family of Debye-Scherrer cones with half-angles of 2θ . In contrast, textured polycrystals often display strong variation of intensity around the azimuthal angle along with a weak variation in the scattering angles since elastic strains in crystalline materials typically do not exceed 1%.

However, elastic strain is not the only nor the principal source of lattice parameter variation, since compositional variations also induce significant changes in the lattice parameters and are widely reported in welds, castings, etc. As a means of avoiding the need to determine the unstrained lattice parameter, the so-called $\sin^2\psi$ method is often employed (Romano-Brandt et al., 2020).

An important aspect of diffraction-based strain evaluation concerns the use of white (polychromatic) X-ray beams that produce scattering patterns consisting of discrete peaks. These patterns (sometimes referred to as *Lauegrams*) contain information about crystal lattice orientation (rotation) and distortion (strain). Recent decades have seen progressive use of X-ray beams focused into tight spots of a few microns and down to 100 nm or smaller. This allows probing intragranular strains and stresses corresponding to

the Type I + II + III sum of components, opening the way to further development of the multi-scale statistical description of these complex distributions of deformation parameters. A key advantage of micro-beam Laue diffraction concerns the ability to obtain information from severely deformed material volumes compared, e.g., with electron diffraction analysis used in EBSD (see below). Important advancements in *Lauegram* evaluation have been achieved by applying DIC to their interpretation that allows higher precision detection of grain rotations and small strains (Petit et al., 2015).

Electron Back-Scattered Diffraction (EBSD) is a well-established electron microscopy technique employed for surface mapping of the sample grain structure and micro-texture evaluation. This is achieved by the analysis of the so-called Kikuchi bands formed by the scattering of conically divergent secondary electron beams originated under sample surface. The detection of small changes in the Kikuchi patterns using DIC analysis to determine elastic strains has become known as HR-EBSD (Wilkinson et al., 2006). Plastic strains cause deterioration of Kikuchi pattern quality that allows qualitative mapping of inelastic deformation but places a limit on elastic strain evaluation due to the loss of fitting accuracy.

An important aspect of EBSD is the possibility of combining it with FIB serial sectioning to obtain three-dimensional maps of grain orientation. This tomographic method provides a resolution of one of the central problems of materials science, namely, 3D visualization of grain structure down to the nanometer level. In principle, this approach can be used for 3D strain evaluation using HR-EBSD, with the following two caveats. Firstly, the act of material FIB removal causes stress re-equilibration and strain redistribution that must be taken into account, e.g., using eigenstrain analysis. Secondly, the process of ion milling may itself introduce additional eigenstrain sources of residual stress and residual elastic strain (Salvati et al., 2016a, b). One of the challenges in implementing this approach lies in the difficulty of identifying or producing a sample with known micro- to nano-scale residual stress-strain state that can be used for validation.

'Rich' tomography of strain and stress

One of the most challenging tasks in residual stress analysis concerns non-destructive evaluation of 3D strain distribution at desired resolution and with adequate statistical reliability. This is most likely achieved using diffraction methods combined with tomographic reconstruction techniques.

Initial feasibility study of strain reconstruction tomography (Korsunsky et al., 2006a,b) made use of the algebraic reconstruction technique applied to strain component aligned with the axis of rotation. This principle later became referred to as the rotational invariance of the scattering pattern. The choice of the axial scattering component allows the reduction of the complex tensor tomography problem to that of a scalar. A subsequent study (Korsunsky et al., 2011) provided demonstration that the strain value determined from the scattering pattern from a pencil-shaped gage volume illuminated by the incident beam equates to the mean of the strain distribution within it. With appropriate data pre-processing this permits determination of the strain distribution within the entire sample cross section which was validated by comparison with numerical deformation modelling.

Collectively, the family of 'rich' tomography techniques can be defined as the reconstruction of three-dimensional fields that take vector, tensor or function (distribution) values. In recent years this has been applied to the analysis of Small Angle X-ray Scattering (SAXS) data to determine fibrillar orientation within polymers and biological tissues.

Influence of residual stress on structural integrity

A range of studies reported in the literature considered the influence of residual stress on structural integrity (Bouchard, 2001). It is often stated that compressive residual stress inhibits the formation of cracks and their growth that leads to component failure, while tensile stress promotes crack formation and reduces safe life. In practice, more detailed and precise consideration of the modes of loading, damage and failure is required for successful residual stress engineering – tailoring material processing to control residual stress for maximum structural integrity under given service conditions.

Structural integrity can be understood as the fracture resistance and load-bearing limit under monotonic, cyclic or long-term loading. Material capacity to withstand external loading depends not merely on the mean (Type I) stress within it, but also on the local peak values representing Type I + II + III applied stresses in combination with residual stresses at appropriate scales.

The approach to residual stress and strain analysis presented above suggests that in the same way as these physical quantities display statistical character and depend on the scale of consideration, so must their limiting values that appear in the criteria for damage initiation and growth or failure. In other words, the presented multi-scale analysis of stresses and strains necessitates scale-dependent structural integrity approach. This methodology is in the early stages of development in such important areas as structural composites, energy storage devices etc., and is expected to undergo a period of active advancement in the coming decade.

Conclusion

The present treatment began with aspects of theoretical description of the multi-scale, statistical distributions of internal stresses and strains within engineering materials and components, particularly using the concept of *eigenstrain*. This was necessitated by the fact that this theoretical framework is indispensable for correct evaluation of residual stress independently of the chosen experimental

approach. Furthermore, statistical description must be employed in a manner that preserves consistency across different scales (Krylov and Bogolyubov, 1937).

A crucial aspect of a valid residual stress state within a sample is that it must comply with volumetric relationships (equations of equilibrium) and surface conditions (traction-free). Accordingly, there has been progression toward residual stress evaluation using eigenstrain-based description that involves the entire object and ensures compliance with the constraints of materials mechanics. It has been shown that the incorporation of eigenstrain confers advantages in the use of established approaches, such as the contour method and residual stress depth profiling using incremental drilling, or FIB-DIC micro-ring core milling.

The presented summary of experimental techniques of residual stress evaluation covered the two principal classes, namely, material removal and diffraction-based methods. State-of-the-art review was followed by the discussion of new and developing approaches, such as 'rich' tomography of strain.

Abstract

A major barrier in the adaptation of additive manufacturing into the realm of accepted manufacturing technologies is the requirement for rapid and standardized approaches for qualification of materials and processes. Terahertz nondestructive evaluation techniques could play a major role in the creation of a standardized qualification process for additively manufactured components. This chapter showcases the current use of terahertz nondestructive evaluation on two emerging material applications: additively manufactured components and multilayer paint stacks.

Key points

- Terahertz nondestructive evaluation techniques could play a major role in the creation of a standardized qualification process for additively manufactured components.
- The current use of terahertz nondestructive evaluation on two emerging material applications are showcased: additively manufactured components and multilayer paint stacks.
- As new materials for additive manufacturing are developed and new printing techniques are created, standardized approaches for rapid qualification of these materials and processes will be required.
- Owing to refractive effects, terahertz nondestructive evaluation is best suited to planar structures. Examples include the material characterization and thickness measurements of multilayer paint stacks.
- Based on the accelerated corrosion studies using salt-fog exposure and humidity cycling, a 5.6% change in the reflectivity from the metallic layer indicates significant chemical corrosion of the multilayer paint coating prior to any visible evidence of a blister on the coating surface. Further chemical corrosion (and commensurate decrease in terahertz reflectivity) leads to detachment of the coating from the substrate.
- The major driving force behind the development of additively manufactured terahertz and microwave components is the development of next-generation wireless communication systems.

- Various terahertz quasi-optical devices including GRIN lenses, topological waveplates, phase plates, polarization splitters, q-plates, and stepped-refractive-index lenses have been fabricated by 3D printing.
- Terahertz imaging can detect defects in additively manufactured structures which could significantly impact their functionality.
- Terahertz computed tomography of additively manufactured parts has many of the same analysis capabilities as X-ray computed tomography: detection of internal voids and defects, measure internal and external geometry, and ability to compare printed parts to their computer-aided design.
- Corrections to terahertz computed tomography analysis to account for Gaussian beam propagation as well as refractive effects have been demonstrated.

Introduction

Terahertz nondestructive evaluation

Terahertz (THz) radiation refers to the range of electromagnetic waves between the microwave and infrared from 0.1 to 10 THz and wavelengths of 3 mm–30 μm (Wang and Zhang, 2004). Technology related to the creation, manipulation, and implementation of these waves within the “THz gap” is still relatively new and not widely utilized. Since THz waves are nondestructive and do not carry enough energy per quantum to ionize the atoms or molecules that are exposed to them, THz radiation offers many benefits over other traditional material evaluation techniques. These frequencies can be used for spectroscopy, imaging, and structural evaluation. There are many ways to generate and detect THz waves. THz systems can employ either continuous wave or pulsed wave configurations. The most common continuous wave systems use photomixing for tunable narrowband generation while pulse-based systems generate a broadband pulse using biased photoconducting antennas (PCA) (Mittleman, 2003).

Nondestructive evaluation (NDE) methods test and inspect various aspects and characteristics of materials, components, and full systems without permanent damage. NDE is extremely useful in various fields of research and industry because it can save time and money by allowing for rapid, successive, and significant assessment without sacrificing the object being inspected. Valuable or rare samples can be spared where other evaluation techniques might damage them (Sathishkumar et al., 2020).

This chapter describes the use of THz spectroscopy and imaging for NDE on two emerging material applications: additively manufactured components and multilayer paint stacks. For the first application, NDE of fused deposition modeling (FDM) printed plastics and nanoparticle jetted ceramics are emphasized. For the second application, NDE is used to determine both the frequency-dependent permittivity and thicknesses of individual paint layers, while also evaluating corrosion which is hidden below the outer paint surface.

Additive manufacturing—Plastics and ceramics

The terms additive manufacturing (AM) and three-dimensional (3D) printing can generally be used interchangeably: they encompass all the processes that create objects or structures by adding material as opposed to removing it in subtractive manufacturing. There are currently seven common types of additive manufacturing: material extrusion, sheet lamination, vat polymerization, powder bed fusion, material jetting, binder jetting, and direct energy deposition (Alfattni, 2022). The specific process chosen depends on the application’s needs. Despite its popularity and promise, AM is currently being held back from becoming a mainstream manufacturing technique by the lack of standards for quality assurance and qualification of the AM parts. Many industries have expressed concern about this lack of standardization, and The National Institute of Standards and Technology (NIST) reports that there are presently no additive manufactured materials or processes that have been specifically qualified for aerospace or critical defense applications (Moylan, n.d.).

In 2021, the United States Department of Defense (DoD) released an updated version of an AM roadmap, originally created in 2016 with *America Makes*, outlining the current objectives of AM and the barriers that must be overcome. Specifically, this roadmap lays out the steps needed to mature the technology of AM in order both for the DoD to fully adopt and utilize this technology, and to allow applications in the public sector. In this current strategy, the DoD identifies the number one barrier to moving AM into the realm of accepted manufacturing technologies as “rapid and standardized approaches for qualification of materials and processes, and certification of AM parts.” Yet, as stated in the original DoD roadmap, additive manufacturing has the ability to become cheaper, faster, and more reliable than most current manufacturing techniques (Fielding et al., 2021). The development of THz NDE techniques for these AM parts can play a major role in the full adoption of this technology through the creation of a standardized qualification process (Joint Defense Manufacturing Council, 2021).

The term “qualification” refers to the fulfillment of requirements in the original design: for example, the final product must satisfy dimension constraints, and a major concern with additively manufactured parts is post-printing material shrinkage. An application example that requires strict dimensional constraints is dental crowns, where research has been performed on creating low shrinkage ratio materials; but even those optimized AM materials show signs of shrinkage of over 2% (Zhao et al., 2021).

In a wide variety of applications, for a product to be functional, evaluation and qualification of its final dimensions is crucial. AM parts frequently have structural defects and internal voids caused by the printing process that are not seen under inspection because the part is not transparent to visible light; but in such circumstances, THz NDE can allow defect detection through non-contact imaging.

THz spectroscopy can also characterize the electromagnetic properties of AM structures and has been proven to be a reliable means for optical property characterization (Yasuda and Hosako, 2008; Yilmaz and Akan, 2020; Waddie et al., 2020; Ruan and Chan, 2019). Recently, there have been advances in using FDM printers to print microwave and THz-based passive optical components including waveplates, phase plates, antennas, and lenses (Rohrbach et al., 2021; Zhang et al., 2017; Siemion et al., 2020). AM ceramic structures have been designed for applications in capacitors, filters, dielectric resonator antennas, and 5G devices (Goulas et al., 2020; Morales et al., 2021). The accuracy, reproducibility, and electromagnetic response of such AM structures will likely depend on the structures' printing parameters, and so the ability to tune properties such as refractive index, attenuation coefficient, birefringence, and relative permittivity will be important. Utilization of THz NDE for printed optical components and their material characteristics will be discussed later in this chapter.

Terahertz NDE is well-suited for the characterization of planar structures, where refractive effects due to curved surfaces are minimized. Moreover, using broad-banded terahertz pulses with time durations in the few picoseconds range results in high spatial resolution in the direction of the pulse propagation (a typical resolution is about 10 μm , which is much smaller than the wavelength of the terahertz radiation). In the transverse direction, the spatial resolution of freely propagating terahertz radiation is limited by Gaussian beam propagation and diffraction to several electromagnetic wavelengths.

THz computed tomography (CT) can be used to create 3D reconstructions of a structure being imaged. Like traditional X-ray CT, THz CT has been implemented for NDE internal structure observation; previous research includes the comparison and evaluation of various reconstruction algorithms using THz CT (Recur et al., 2011). But to date, little research has been done utilizing THz CT on 3D printed structures, although various correction algorithms have been created to correct for refraction losses and Fresnel reflection boundary effects observed when utilizing THz for CT (Abraham et al., 2010; Mukherjee et al., 2013). If implemented, THz CT of AM structures could be useful in rapid prototyping, failure analysis, and material characterization.

THz NDE of multilayer paint stacks

An important example of THz NDE of planar structures is the study of multilayer paint systems. Terahertz waves can penetrate many non-conductive materials, enabling a contactless testing method. In such studies, terahertz time-domain reflection measurements are sometimes referred to as terahertz pulse imaging (TPI). In its simplest form, the THz-TD transmitter emits a near-single cycle electromagnetic pulse with a bandwidth from ~ 0.1 to 3 THz. This extremely wide bandwidth pulse is focused on the coating, and echo pulses are generated from each interface (air-layer, layer-layer, layer-substrate). The terahertz radiation penetrates the whole coating stack and samples the properties of each layer provided that the layer is not metallic. By analyzing the reflected THz pulse, one can reconstruct the thicknesses as well as the permittivity ϵ and permeability μ of each paint layer. Equivalently, one can characterize the properties of each layer through its complex refractive index $\tilde{n} = \sqrt{\epsilon\mu/\epsilon_0\mu_0}$ where ϵ/ϵ_0 and μ/μ_0 are the permittivity and magnetic permeability of the paint layer relative to a vacuum.

Over the last 15 years, terahertz nondestructive evaluation and imaging has found application to various multilayer coating structures (paints and ceramic coatings) for several industries including aerospace and automotive (Krimi et al., 2016; Krimi et al., 2017; Catapano et al., 2017; Bohn and Petkie, 2013; Su et al., 2014; Ellrich et al., 2020; Stoik et al., 2008; Yasuda et al., 2007; Su et al., 2014). More specifically, it has been used as a method for the testing of dried paint layers on automotive vehicles for quality control as well as determining the thickness of the paint layers (Takeshi Yasui et al., 2005; Yasuda et al., 2006; Federici, 2012; Yasuda et al., 2007; Su et al., 2014; Krimi et al., 2016). As pointed out by Krimi et al. (2017) materials for coatings and substrates are continuously improved requiring concomitant improvements in quality control and thickness monitoring technologies. Examples of substrate innovations over standard metals include carbon fiber-reinforced polymers and glass fiber-reinforced polymers. In many cases, the substrate materials are highly reflective, thus requiring that terahertz NDE be performed in a reflective mode. Terahertz techniques are effective not only for measuring the frequency-dependent permittivity and thicknesses of the various layers but also for detecting the presence of defects.

Additive manufacturing

This section mainly focuses on the use of FDM printing and nanoparticle jetting for AM, but all AM follows a general order-of-procedures to 3D print an object. First, a 3D model of the structure is created using Computer-Aided Design (CAD) software. The model is then transferred to slicing software, where the different structural parameters are chosen. The structure's infill, layer heights, size, orientation, and other parameters can be altered. The slicing software then converts the model into a programming language called G-code which commands the printer to print the model (Evans, 2012) in a hands-off process to complete the part. Once an object or sample has been printed, THz NDE can be employed.

The major driving force behind the development of additively manufactured terahertz and microwave components is the development of next-generation wireless communication systems (Federici et al., 2016; Federici et al., 2013; Federici and Moeller, 2010). Since these additively manufactured components are designed specifically to focus, split, and otherwise manipulate terahertz radiation, it is critical to characterize the refractive index, attenuation, and birefringence of the component materials in the terahertz frequency range. Aside from terahertz optical components, THz NDE is important for material characterization of additively manufactured materials—such as polymers, ceramics, and composites. Using THz NDE, images of the structure can be taken, optical properties of the materials can be characterized, defects in the structures can be discovered, 3D computed tomography models can be created, residual stresses in the structures can be mapped, etc. Generally speaking, the end goal is to qualify the additively manufactured part—does it function (physical dimensions, mechanical stress, porosity, etc.)—as designed?

THz spectral characterization of materials

THz NDE has the capability to characterize different optical properties of materials. Analysis of the THz waves can be implemented in the time-domain, for example, by measuring the time delay of a waveform or in the frequency domain via the Fourier transform of the time versus THz electric field measurements (Mittleman, 2003). By taking the discrete Fourier transform (DFT) of measured voltages, using a Fast Fourier Transform (FFT) algorithm, the time domain data can be represented in the frequency domain for analysis. Using frequency domain data, the complex refractive index, transmission coefficient, attenuation coefficient, relative permittivity, and birefringence of THz transparent materials can all be measured. For calculation of the complex refractive index of a material, while considering the sample's thickness, three THz waveforms are required: an averaged sample waveform, a reference waveform, and a background waveform. The reference waveform usually consists of the measured time-domain waveform with either the sample removed (for a transmission geometry) or the sample replaced by a perfect mirror (for a reflection geometry). The background waveform corresponds to a measured offset in the time-domain waveform which is recorded when the THz beam is blocked. Subtracting the background waveform from the sample waveform removes the offset.

The time-domain waveform data is converted to the frequency domain via a Fourier transform to calculate both the real and imaginary parts of the refractive index as a function of frequency. The phase angles as a function of frequency are calculated for both the averaged sample and reference waveforms and are used to calculate the frequency-dependent real refractive index $n_r(\nu)$ using the relationship

$$n_r(\nu) = 1 + \frac{c_0 \Delta\phi(\nu)}{2\pi L \nu} \quad (1)$$

where c_0 is the speed of light, $\Delta\phi(\nu)$ is the frequency-dependent phase difference between the sample and reference waveforms, L is the thickness of the sample measured, and ν is the frequency. Once the frequency-dependent real refractive index is calculated, it is possible to select a specific frequency at which to compare the real refractive indices.

Since most non-conductive plastic samples are relatively transparent in the THz frequency range, the imaginary refractive index is small compared to the real refractive index. The measured amplitude of the transmitted THz Fourier transform can be corrected for Fresnel reflection losses at the air-sample and sample-air interfaces (Prabhu, 2018). Using the real refractive index to correct for losses at the boundary, the imaginary refractive index can be calculated using

$$n_i(\nu) = \frac{c_0}{2\pi \nu L} \ln \left(\frac{|E_R(\nu)|}{|E_S(\nu)|} t_{12} t_{21} \right) \quad (2)$$

where $|E_R(\nu)|$ and where $|E_S(\nu)|$ represent the magnitudes of the DFT of the electric field measurements of the reference and sample waveforms, respectively. The Fresnel transmission coefficients at normal incidence between air and the sample and the sample and air are represented by t_{12} and t_{21} and are calculated using

$$t_{12}(\nu) = 2/(1 + n_r(\nu)) \quad (3)$$

and

$$t_{21}(\nu) = 2n_r(\nu)/(n_r(\nu) + 1). \quad (4)$$

The attenuation coefficient can be calculated using the resulting corrected imaginary refractive index by

$$\alpha = 2\pi \nu n_i / c_0. \quad (5)$$

The frequency-dependent refractive indices and attenuation coefficients for many common 3D printable plastics have been previously characterized (Castro-Camus et al., 2020; Clark et al., 2021).

Additively manufactured THz optical components

Using the THz spectral measurements in combination with AM, recent studies have shown that it is possible to create operable microwave and THz optical components. One of the technical applications driving the push to develop low-cost terahertz and sub-terahertz components is the shift of wireless communications from the currently used few GHz bands to higher carrier

Fig. 1 Examples of 3D printed terahertz components. (a) A Gradient-Refractive-Index (GRIN) lens (b) topological waveplate. From Castro-Camus E, Koch M and Hernandez-Serrano AI (2020) Additive manufacture of photonic components for the terahertz band. *Journal of Applied Physics* **127**: 210901.

frequencies in the several hundreds of GHz band (Federici et al., 2016; Federici et al., 2013; Federici and Moeller, 2010). Several research teams have succeeded in creating various THz quasi-optical devices fabricated by 3D printing. Fig. 1 shows examples of a 3D printed gradient-index (GRIN) lens as well as a topological waveplate. Because the resulting refractive index and birefringence of these materials could be measured using THz NDE, it was possible to tailor these lenses for specific applications (Castro-Camus et al., 2020). As another example, Fig. 2 shows experimental nylon polyamide (PA6) diffractive lenses and their resulting irradiance measured at the plane of the lens—another successful implementation of using FDM for the creating of THz-based optical components (Furlan et al., 2016). Many other THz optical components (including phase plates (Rohrbach et al., 2021), polarization splitters, q-plates, and stepped-refractive-index lenses (Serrano, 2018)) have also been created using AM for the terahertz frequency range.

The AM fabrication process of terahertz optical components presently suffers several limitations. Currently, there are only a limited number of materials that are usable within FDM 3D printers, and even fewer whose transparency is within a usable range (Castro-Camus et al., 2020). For example, polylactic acid (PLA) is a common 3D printed plastic, but unfortunately, it exhibits a high absorption in the terahertz frequency range. Consequently, unless the material is very thin, it will not transmit sufficient terahertz radiation to be functional. Some of the currently used polymers for the manufacturing of terahertz optical components include high-density polyethylene (HDPE), polypropylene, polystyrene, TOPAS (also known as cyclic olefin copolymer (COC)). Most of these polymers exhibit relatively minimal attenuation, but also have refractive indices close to 1.5. A consequence of this similarity of refractive indices is that certain optical components, such as photonic crystals with large bandgaps (where a significant refractive index contrast is required), are very challenging to print.

Another limitation of current economically viable FDM 3D printers is their relatively poor resolution. Since the resolution of these printers is still relatively coarse, the resulting printed optical components must operate within the low range of a few hundred gigahertz, the low end of the THz band. Other types of AM such as stereolithography (SLA) resin printers can produce higher resolution prints, but generally they are much more expensive, and the compositions of the materials may be proprietary. Yet, as FMD technology progresses and evolves, more polymers will be adapted, and the resolution will improve, allowing for increased quality in optical component fabrication (Castro-Camus et al., 2020).

THz NDE of additively manufactured components

In this section, several THz NDE modalities for characterizing additively manufactured components are described. The modalities focus on key aspects of component specification:

- THz for infill structures—Internal infill structure and infill percentage are major considerations for the structural and mechanical strength of 3D printed components.
- THz imaging for defect detection—Defects in the 3D printed structures could significantly impact their functionality. Simple examples include cracks/ voids in the printed structure or regions of high mechanical stress.
- Effect of print parameters on THz properties—3D printing parameters can have an effect on the resulting optical properties of the final printed structure. The ability to fine-tune the optical properties of these structures including refractive index, attenuation coefficient, and birefringence is crucial to the design and fabrication of various optical components.
- THz CT—A complete 3D image of an AM part could enable a detailed comparison of design versus printed dimensions, structural defects, etc. THz CT of AM parts has many of the same analysis capabilities as X-ray CT: detection of internal voids and defects, measure internal and external geometry, and ability to compare printed parts to their CAD design. However, THz CT

Fig. 2 Examples of 3D printed THz diffractive lenses. (a) Fresnel, (b) fractal, and (c) Fibonacci models. The corresponding maps of THz irradiance measured at the plane of the lens are shown in the second column of images. exhibits some challenges as well as advantages when compared to X-ray CT. Challenges include correcting for refraction of THz rays, Gaussian beam profiles, and more limited spatial resolution. However, THz enables an additional modality which X-Ray CT does not: visualization of stress/strain in the printed part through the photoelastic effect.

- THz birefringence—Clearly, characterizing the birefringence of additively manufactured materials is an important parameter for 3D printed terahertz components. The birefringence, typically manifested through a photoelastic effect—can be either intrinsic due to residual internal stress within the material or induced via an externally applied stress. For some components, such as additively manufactured lenses, one would typically require minimal birefringence. For other components such as those whose functionality is dependent upon the phase delay of propagating terahertz waves, the ability to fabricate structures with a controllable birefringence might be important.

THz NDE of infill structures

Key structural and mechanical strength considerations of 3D printed structures are the internal infill structure and infill percentage. Terahertz time-domain imaging of 3D printed infill structures (Busboom et al., 2021) shows that THz NDE can be used to visualize the infill structures. Useful imaging modalities include both transmitted power in a frequency band as well as pulse time-of-flight measurements. Transmission measurements are easier to implement, but are limited if the material is too thick (ABS which was used in (Busboom et al., 2021) to fabricate the structures exhibits a large absorption in the terahertz range) or the infill structure is too complex. Reflection measurements are useful to determine which grid direction is printed first enabling a clearer visualization of the infill structure. While these results are interesting, the samples under study were oriented such that the walls of the infill were always perpendicular to the propagating terahertz beam direction. An arbitrary orientation of the infill structure relative to the beam direction would require a computed tomography modality to render a 3D image of the infill structure.

THz imaging of defects

As an example of defect imaging, NDE of ceramic samples is presented (Clark et al., 2021) in this section. The samples were fabricated using an XJet Carmel 1400 nanoparticle jet printer. Nanoparticle jetting is a proprietary printing technology developed by XJet, which falls under the category of binder jetting additive manufacturing. ZrO_2 nanoparticles are suspended in a polymer binder and carrier agent to form an ink. As multiple print nozzles deposit layers of the ZrO_2 dispersion on top of one another, as well as support structure material, the carrier agent is evaporated and the layers are dried using heat lamps and hot air dryers. The support material is dissolved from the print by submerging the structure in water. After a period of drying in a desiccating chamber, the samples are ready for sintering. Processing above 1200 °C is required to convert the mixture of monoclinic and tetragonal phases into a mixture of tetragonal and cubic phases and join the individual ZrO_2 particles into a dense ceramic structure. Voids form as the polymer binder decomposes, where the size, shape, and distribution of these defects depend upon the maximum firing temperature. The samples used in this example were all printed with identical printing parameters, but experienced different maximum firing temperatures varying from 750 °C to 1450 °C in increments of 100 °C. The samples were 50 mm², 2–3 mm thick, with printed layer thicknesses of 10 µm, and a jetting resolution of roughly 20 µm.

The relative permittivity of the extruded ceramics was measured by mounting the samples to an XY gantry away from the focal point of the lens. This was done to create a larger spot size interacting with the samples in a transmission configuration. The samples are measured between 60 GHz and 3 THz using the T-ray 5000 system using an average of 2000 acquired THz waveforms. Valid data is extracted between 110 GHz and 550 GHz due to the low signal-to-noise ratio. To show and verify that this data is accurate and repeatable, the samples are also measured between 75 GHz and 110 GHz using a free-space focused beam system.

The data in Fig. 3 from the free-space system matches the T-ray 5000 data very well, confirming that these are accurate measurements. This data confirms that as a product of increased firing temperature, the relative permittivity increases, while not

Fig. 3 Relative permittivity of the various sintered ceramic samples at different sintering temperatures showing data between 75 GHz and 550 GHz provided by Paul Parsons. “Green State” refers to an un-sintered sample. From Clark AT (2022) *Nondestructive Evaluation of 3D Printed, Extruded and Natural Polymer Structures using Terahertz Spectroscopy and Imaging*. Ph.D. Doctoral Dissertation, New Jersey Institute of Technology.

varying over a relatively large frequency range. At temperatures above 1200 °C, where the structure conversion takes place, the relative permittivity reached a value where the increase between samples decreased dramatically, almost to zero.

Small location-dependent variations in the relative permittivity were observed when the THz beam was focused over a small spot size on the sample. Images were taken by raster scanning the samples in a transmission configuration to investigate these variations. The contrast of the images shows the variations in the dielectric constant of the material at each pixel. As the particles begin to sinter, and voids begin to disappear with increasing temperature, all the samples show clear isotropic volume reduction. The samples decrease in volume from 1% up to 18% at the highest sintering temperature of 1450 °C. There are also numerous horizontal striations seen in all the samples. An alignment issue with the XJet printer, verified by Xjet staff, was the cause of these striations, resulting in a major flaw throughout each of the prints. The flaws shown in Fig. 4, a consequence of misaligned print heads, are effectively an inhomogeneity in the dispersion of the ZrO₂ particles.

In the 1450 °C sample, a dark wavy horizontal feature about one-third of the way down is visible, marked by the white arrow. This is a crack that runs throughout the entire length of the sample. A combination of material shrinkage and inhomogeneous particle density caused by the misaligned print heads is to blame. More importantly, this crack is not fully visible under visual inspection. With post THz imaging, only then the full extent of the crack was observed. This is a clear and successful application of using THz NDE for both electromagnetic property characterization as well as the detection of defects within AM ceramic structures.

Effect of 3D printing parameters on FDM printed components

When printing optical components such as the GRIN lens or diffractive lenses shown in Figs. 1 and 2, it is important to know if the printing parameters will have any effect on the resulting optical properties of the final structure. When any structure is printed, there are multiple different parameters that are either automatically chosen by the slicing software or manually picked by the user. The ability to fine-tune the optical properties of these structures including refractive index, attenuation coefficient, and birefringence will rest on detailed knowledge of such dependencies (Alfattni, 2022). Commonly altered printing parameters include the printer's nozzle size, the layer height within the print, or a print's orientation. For example, if the refractive index of a 3D printed terahertz lens varies with printing parameters, then the focal length of the lens would be dependent on printing parameters. Likewise, if the attenuation depended on printing parameters, then the throughput transmission of the lens would be dependent on the printing parameters as well. Similarly, if the refractive index, attenuation coefficient, or birefringence of a printed THz waveguide were to vary due to printing parameters, then the device performance (e.g. propagation speed of guided terahertz, numerical aperture of the waveguide, loss per unit length of the waveguide) would all be dependent on the various printing parameters.

Refractive index, attenuation coefficient, and level of birefringence have been measured for a set of 3D printed samples printed with various printing parameters (Clark et al., 2021). The samples were rectangular blocks of various clear filaments printed using a commercial 3D printer. Changes in the optical properties of these printed structures are observed and compared. The THz optical properties of the materials studied here have previously been demonstrated to be frequency-dependent. Optical property changes have been isolated at 500 GHz. At this frequency, there is a good signal-to-noise ratio and lack of interference oscillations in the measured data.

Table 1 shows the variation based on changing the print orientation of the structure. The print orientation dictates whether the rectangular block sample was printed either laying down (horizontal) or up on edge (vertical). By changing the print orientation, the planes in which individual layers are printed are altered. There is a clear correlation between print orientation and change in refractive index: an average increase of 1.9% in the real refractive index at 500 GHz when the samples are printed horizontally compared to vertically. Three of the four measurable attenuation coefficients have increases greater than the calculated uncertainty.

Fig. 4 Raster scan images of the dielectric constants of varying sintering temperature ZrO₂ samples. Horizontal striations seen throughout are a result of print head misalignment during the printing process. A crack in the 1450 °C is indicated by the white arrow. From Clark AT (2022) *Nondestructive Evaluation of 3D Printed, Extruded and Natural Polymer Structures using Terahertz Spectroscopy and Imaging*. Ph.D. Doctoral Dissertation, New Jersey Institute of Technology.

Table 1 Real refractive indices and attenuation coefficients of samples at 500 GHz based on variation in print orientation (Clark et al., 2021).

Filament Material	Print Orientation	Real Refractive Index (n)	Attenuation Coefficient (cm^{-1})
PLA	Horizontal	1.654	4.429
	Vertical	1.604	5.092
Nylon	Horizontal	1.749	4.015
	Vertical	1.741	4.099
PC	Horizontal	1.649	1.944
	Vertical	1.623	2.444
CPE	Horizontal	1.683	3.343
	Vertical	1.650	3.191
PP	Horizontal	1.492	N/A
	Vertical	1.457	N/A

Note: Standard printing parameters of a 0.4 mm nozzle and 0.2 mm layer heights were used. Uncertainties in the real refractive index: $2\sigma = \pm 0.010$ and attenuation coefficient: $2\sigma = \pm 0.025$.

From Clark AT, Federici JF and Gatlery I (2021) Effect of 3D printing parameters on the refractive index, attenuation coefficient, and birefringence of plastics in terahertz range. *Advances in Materials Science and Engineering* **2021**: 8276378.

Fig. 5 Level of birefringence ($\frac{\Delta n}{n}$) measured at 250 GHz in vertically printed samples using a 0.4 mm nozzle and standard printing parameters with variation of print layer height. From Clark AT, Federici JF and Gatlery I (2021) Effect of 3D printing parameters on the refractive index, attenuation coefficient, and birefringence of plastics in terahertz range. *Advances in Materials Science and Engineering* **2021**: 8276378.

The samples were cut and their cross sections were viewed using a light optical microscope but no air gaps within the prints were discovered. It is plausible that the surface texture differences between the horizontal and vertical samples might cause these correlations. In a vertically printed sample, the THz beam is interacting with a repeating structure surface layer with features of similar size to its wavelength. Previously reported, increasing the surface roughness of various samples measured in the THz range has increased the uncertainty of thickness measurements as well as increased the measured values of real refractive indices (Burger et al., 2021; Fukuchi et al., 2013). Changes in the refractive index and attenuation coefficient based on a change in nozzle size and layer height were also measured and are shown in Clark et al. (2021).

Using the same samples, the birefringence dependent on varying printing parameters was also measured. Vertically printed samples show birefringence levels above the experimental uncertainty and are shown in Fig. 5. As the layer height of the samples increases, the birefringence present in the sample also increases. This trend is seen in every filament material. Additional stresses may be induced into the material as it is rapidly heated and cooled from printing temperature back to room temperature during the FDM 3D printing process. These large thermal fluctuations combined with forced extrusion could create a birefringence within the final structure as the layers are deposited on top of one another. Increasing in nozzle size from 0.4 mm to 0.8 mm causes an average of 125% decrease in birefringence, shown in (Clark et al., 2021). One possible explanation for this decrease is that with the larger nozzle size each layer of the sample is printed faster and, since each layer is printed faster, there is less elapsed time for that layer to cool. With shorter time between layers, there will be a decrease in the introduction of residual stresses into the material due to thermal differences between those layers. As shown in the slower printing 0.4 mm nozzle samples, thermal differences between layers will create a larger measurable birefringence than the faster printing 0.8 mm nozzle layers (Clark et al., 2021). These measurements showcase another application of THz NDE; the ability to measure and track changes to important optical characteristics of AM structures.

Refractive effects

THz radiation will undergo refraction when entering a sample at any angle other than normal incidence. This refraction leads to a redirection of the beam that needs to be accounted for in image reconstruction. This shortcoming can be mitigated in some cases using an index matching material. This material, typically a fluid, can be used to surround the sample, and be shaped in such a way as to create boundaries of normal incidence that couple the THz radiation into the sample by minimizing refraction and reflection of the beam as it interacts with the sample.

A simple example is provided by the study of insects embedded in ancient amber. Samples of Dominican amber (in which ancient termites are sometimes encased) typically have an irregular rounded shape. In order to remove most of the topological refractive effects, the round sample of amber is suspended in a cubical container filled with a liquid of similar refractive index to the amber, such as mineral oil. Under a perfect refractive index match, the surface topology of the sample will vanish because there will be no reflections from the surface of the sample, allowing inclusions within the sample to be studied free from distortions. Fig. 6 shows a measurement using a closely matched refractive index fluid to minimize the refractive effects caused by the amber matrix. Alternative methods of refractive correction algorithms are discussed in the next section.

THz computed tomography of additively manufactured components

The approach of 3D image reconstruction using computed tomography (CT) is illustrated using the parallel ray configuration of Fig. 7 to image a slice of an object. The line scans, which are a collection of measurements along parallel ray paths, are called projection measurements. The measured quantity can be transmission, absorption, time-of-flight, refractive index, or some other electromagnetic quantity. A projection measurement is a set of line integrals that represent the interaction between the incident radiation and the medium represented by a 2D function $f(x,y)$ that it interacts with and transmits through along one axis of measurement. Projection measurements are performed at multiple rotation angles θ . These projection measurements are the primary source of data for the tomographic reconstruction of the 2D slice through the object. Full 3D reconstruction is achieved by translating the object perpendicular to the page and acquiring data for each 2D slice.

Fig. 6 (Left) Dominican amber sample. (Right) 0.5–2 THz frequency range integration image of the amber sample submerged in Fisher Scientific pure mineral oil, a closely matched refractive index fluid, to reduce refractive effects (Clark, 2022).

Fig. 7 Illustration of a parallel beam projection measurement where $f(x,y)$ is the two-dimensional (2D) function representing the sample and $R_\theta(x')$ is the resulting projection measured at angle θ (Clark, 2022).

A Radon transformation is a linear operator used to take a known function f in a 2D coordinate plane and represent it in what is known as the projection domain. A projection of an object can be represented by the sum of several sine waves. At each measured z value (see Fig. 7), a set of projections from discrete angles is then formed into a 2D representation of the object in the projection domain known as a sinogram (Taubmann et al., 2018). A sinogram is a stack of projection measurements that can be used to construct a tomographic image of the structure that was scanned.

Converting the sinogram measurements to a reconstructed tomographic image is an inverse problem. The sinogram measurements are used in various reconstruction methods such as the standard filtered back-projection (FBP) algorithm, iterative techniques such as the algebraic reconstruction technique (ART), or an even faster simultaneous algebraic reconstruction technique (SART) to create 2D tomographic images (Dhawan, 2003; Recur et al., 2011). Iterative reconstruction methods generally result in more accurate reconstructions but require much more computational power and time. The tomographic images, or “slices”, are top-down views of the selected plane through the object scanned. By stacking these individual tomographic images and utilizing reconstruction software, it is possible to create a 3D reconstruction of the structure based on the chosen optical property or waveform attribute that was measured.

Despite the commonality of approach between X-Ray and THz CT, there are some major distinctions in applying computed tomography in the two different spectral regions. X-ray CT is much simpler than THz CT because X-Ray radiation travels through the target material in almost straight lines without much refraction, but THz waves are susceptible to refraction and loss of signal from boundaries: specifically, due to refraction at boundaries, reconstructed THz-CT images exhibit enhanced attenuation at the boundaries and also a distortion of the boundary shapes. Examples of the boundary effect can be seen in many papers on THz CT imaging (Ferguson et al., 2002; Mittleman et al., 1997; Zhang, 2003; Wang and Zhang, 2004; Chan et al., 2007). When elementary back-projection of filtered-projections (BFP) image reconstruction is utilized, only in the case of a low refractive index contrast material (Li et al., 2012; Kim et al., 2012; Lee et al., 2012; Nishina et al., 2012) can the refractive and reflective effects be ignored in the image reconstruction. Refraction of THz radiation by materials—unless the material is immersed in an index matching material—is therefore an inevitable aspect of THz CT.

Perraud et al. (2016) used THz CT to inspect 3D printed components for biomedical implants (PEEK) as well as for aviation components (polyamide). Their CT reconstruction algorithm accounts for a THz Gaussian beam profile. They observe that the finite beam size effect convoluted with the geometric effects (that is, the deflection of the THz beam by the refraction) distorts the reconstructed images and leads to a “systematic over-evaluation of the measured external dimensions and underestimation of the internal ones.”...“After interaction with the object, [the] refraction effect of the THz beam makes it difficult to properly identify the amplitude since an important part of the signal is lost out of the detector. Moreover, each interface and nonparallel surfaces accentuate refraction losses and explain the discrepancies obtained for internal diameter measurements.”

A small number of papers have studied the refraction/ boundary artifacts phenomenon and have tried to remove the prominent boundary effect phenomena by different methodologies. Abraham et al. (2010) introduce a multi-peak averaging method to eliminate boundary effects due to refraction losses of the THz beam inside the material. In applying this technique to 3D THz-CT images of a Teflon (refractive index 1.37) cylinder with a hole on it, the effect of the boundaries is reduced, but the boundaries are still visibility enhanced in the reconstructed image.

Using a completely different methodology, (Mukherjee et al., 2013) showed that by correcting for the two most dominant phenomena (i.e. steering of the THz beam and Fresnel reflection) prior to image reconstruction using filtered backpropagation, the boundary effect can be essentially eliminated. If the shape and refractive index of a ‘standardized’ object were known a-priori, then in principle the effects of Fresnel reflection and refraction would be removed from CT projection data prior to applying filtered backpropagation to reconstruct the image. Because the desired shape and materials of 3D printed structures are known a priori, it is possible to correct for the refraction effects of terahertz beam propagation.

More advanced image reconstruction methodologies are better suited to address the refraction effects of terahertz beam propagation. As an example, consider a more complicated structure such as the “C” shaped structure in Fig. 8 in which direction of a THz ray changes several times as it propagates through the structure. The BFP image reconstruction approach is not valid since the individual rays are not straight lines. The refraction from additional material boundaries in the ray’s path might result from complicated surface geometries, printing infills less than 100% (i.e., not a solid object), or from the use of different materials and consequently different refractive indices in the printed structure. Clearly, for more complicated structure, another method such as Algebraic Reconstruction Techniques (ART), Landweber iteration, or SART (Dhawan et al., 2008; Dhawan, 2003; Tepe et al., 2017; Posodeder et al., 2022) rather than filtered backpropagation is required to reconstruct THz CT images.

As illustrated in Fig. 8, an ART reconstructive grid is defined with each pixel corresponding to a spatial location of the object to be imaged. Optical properties (e.g., absorption or refractive index) of the material are associated with each pixel location. If one propagates an X-ray through the structure (i.e., no refraction for Ray A), the ray sum p_i in the projection data can be expressed as

$$p_i = \sum_{j=1}^N w_{i,j} f_j \quad (6)$$

where $i = 1, \dots, M$ and M is the number of projection rays. The weighting function $w_{i,j}$ represents the contribution from each pixel to the ray sum. The representation of Eq. (6) yields M equations for the N unknown pixel values. Conceptually, the pixel values are determined by comparing the measured projection ray values to those calculated from Eq. (6) and minimizing the error. For each iteration to minimize the error, the difference between the computed ray and measured projection ray sums is calculated and then distributed among the pixels in a weighted manner prior to the next iteration.

Fig. 8 Reconstruction grid with two rays which would define path sums for ART for rays passing through the “C” shaped structure. Ray A (black) illustrates ray propagation through the structure with no refraction present (e.g., X-Ray) and while Ray B (red) illustrates propagation with refraction present (e.g., THz).

In the generalized implementation of ART, the iterative process is initiated by pre-assigning values for each pixel. However, one can take advantage of the fact that for 3D printed components, the design values for the geometry and material properties of the 3D printed components are known a priori. Hence, the initial values for each pixel can be determined from the 3D design files for the component. Furthermore, one can integrate geometric ray tracing of the rays through the reconstruction grid to account for changes in the direction of an individual ray due to refraction as it propagates through the structure. Essentially, one needs to iteratively update both the ray paths and the optical properties of the pixels to reconstruct the THz CT image. Note that with this ART approach, multiple changes in the direction of a propagating ray due to refraction can easily be included as well as Fresnel reflection losses from boundaries. There is no longer the requirement, as is routinely assumed in conventional THz CT, that the THz rays propagate as straight lines through the test object.

Fig. 9 compares using three different reconstruction methods including back-projection of filtered-projections (BFP), simultaneous algebraic reconstruction technique (SART) reconstruction, and an ordered subsets expectation maximization (OSEM) method. These different reconstruction methods were used to create reconstructions of a white foam parallelepiped with two

Fig. 9 Successful 3D CT reconstruction using THz NDE (240 GHz frequency) showcasing the differences between three different reconstruction methods. metal bars throughout. Different types of reconstruction methods are created to reduce or eliminate artifacts in the reconstructions. For example, BFP suffers largely from terahertz beam refraction that needs to be accounted for using corrective algorithms. This experiment was performed to show the ability in visualizing the internal structure of the foam nondestructively, while also showcasing the first application of SART and OSEM to THz CT (Recur et al., 2011). Fig. 10 shows THz CT being used on two different polymer tubes and a polymer tumbler. This figure is comparing the difference between using a Gaussian and Bessel beam for BFP reconstruction. It is shown that in these tomograms the Bessel beam reduces the effects of refraction at the boundaries allowing for a closer reconstruction to the original sample (Wang et al., 2022).

The accuracy to which complex shapes can be resolved using ART techniques is shown in Fig. 11 (Posodeder et al., 2022). Using the design geometry as an a priori guess as to the shape and refractive index properties of the 3D printed structure, geometric optics (i.e., Snell's law) is used to propagate the terahertz radiation through the 'guess' reconstructed structure in order to mathematically correct for refractive effects. Based on a minimization of the error in comparing the measured and reconstructed image, the initial guess as to the shape and refractive index properties of the object are updated for the next iteration in the optimization algorithm. The L1 regularization algorithm, which assumes that large parts of the sample consist of air, produces a reconstructed image whose wall thicknesses most closely match the physical sample.

Another limitation in THz CT compared to X-ray CT is its spatial resolution. Since the wavelength of terahertz radiation (300 μm at 1 THz) is much larger than the wavelength of X-rays, the spatial resolution of X-rays can be significantly better due to diffractive effects. As an example, Ref. (Markl et al., 2017) compared the performance of X-ray and THz CT on pharmaceutical solid dosage forms. Two dosage forms were fabricated by FDM; a single compartment structure with a nominal shell thickness of 0.7 mm and a two-compartment structure with each shell 1.4 mm thick. A key challenge in additively manufactured pharmaceutical dosage forms is the quality control of each single dosage unit. Their results show that X-ray CT provides very detailed information about the microstructure and defects in the 3D print. However, due to the long acquisition and reconstruction times of X-ray CT images, it is not feasible to perform quality control on every printed dosage form. While terahertz imaging, due to its rapid acquisition of depth profiles, could enable quality control of a much larger number of samples, there is insufficient spatial resolution in the terahertz images to extract the essential information about the microstructure.

Fig. 11 Results of a 2D THz CT reconstruction of a 3D printed polypropylene double tube sample. (A) The nominal design structure including the thicknesses of the tube wall. Three different image reconstructions of the sample using (B) Landweber iteration plus a default model as implemented in (Fosodeder et al., 2021). No refractive corrections are included (c) Landweber iteration with refraction corrections and (d) L1 regularization with refractive corrections. The last reconstruction gives the most accurate wall thicknesses. Despite the limited spatial resolution of THz CT compared to X-ray CT, there are complementary approaches one might use to offset the limited spatial resolution of terahertz imaging. For the present example, in which the microstructure and porosity are critical to the functionality of the dosage form, one might be able to employ an index matching fluid to fill in open pores. Introduction of the index matching fluid would reduce the scattering from the porous material enabling a quantitative evaluation of the microstructure and porosity (Naftaly et al., 2020).

Birefringence

It is well-known that stress-induced birefringence occurs in many transparent materials when load is applied (Hecht, 2017). Consequently, the stress-induced birefringence enables photoelasticity measurements to experimentally visualize stress analysis in transparent material (Dally, 1978). In a stress-less experiment with an isotropic (non-birefringent) material placed between two polarizers whose transmission axes are orthogonal, the light which passes through the first polarizing filter maintains its polarization as it propagates through the isotropic material; therefore no light emerges from the second crossed polarizer. However, if the material experiences either applied stress or intrinsic stress, the induced birefringence rotates the plane of polarization of light propagating through the material resulting in some transmission through the second crossed polarizing filter.

The advantage of using terahertz radiation rather than visible radiation for birefringence measurements is that terahertz radiation can be used to probe non-metallic materials which are opaque to visible light. Example materials include plastics, ceramics, as well as composite materials. Several experimental configurations of terahertz birefringence instrumentation have been demonstrated including a very simple measurement in which the arrival times of terahertz pulses with various polarization orientations are measured (Clark et al., 2021). From the difference in pulse arrival times for various polarization orientations, the magnitude and direction of sample birefringence may be calculated.

A cross-polarizer experimental geometry as introduced by Kang et al. (2021) enabled precise birefringence measurements in the terahertz frequency range. Fig. 12 illustrates the relative orientations of the polarizers as well as the relative orientation of the fast

Fig. 12 Experimental configuration for measurement of birefringence in a transmission mode. (a) relative positions of the transmitter/polarizer P1 module, birefringent sample, and receiver/polarizer P2 module. (b) orientation of transmission axes of polarizers P1 and P2, relative to the laboratory horizontal x-axis. The terahertz pulse is propagating into the page. The fast σ_1 and slow σ_2 axes of the birefringent material are assumed to be orthogonal.

and slow refractive index axes of the sample. Rather than analyzing the polarization properties of the transmitted terahertz waves in Fig. 12 using a Jones Matrix approach (as was performed in Kang et al., 2021), here an alternative method is used which is more amenable to the time-domain.

For simplicity, it is assumed that the sample can be treated as a uniaxial birefringent material in which the principle stress axes are perpendicular to the propagation direction of the terahertz waves. The electric field after transmission through polarizer P1 in Fig. 12 can be expressed as

$$E_{TX} = E_{inc}(t)(\hat{x} \cos \phi + \hat{y} \sin \phi) \quad (7)$$

where ϕ is the angle between the horizontal x-axis and the transmission axis of polarizer P1. As the terahertz pulse enters the sample, the vector components of the electric field are written in terms of the basis vectors of the fast (lower refractive index) and slow (higher refractive index) of the material with the fast axis oriented at an angle θ with respect to the horizontal x-axis:

$$\hat{x} = \hat{\sigma}_1 \cos \theta - \hat{\sigma}_2 \sin \theta \quad (8)$$

$$\hat{y} = \hat{\sigma}_1 \sin \theta + \hat{\sigma}_2 \cos \theta \quad (9)$$

The electric field just as it enters the sample, using Eqs. (7–9), can be expressed as

$$E_{s_in}(t) = E_{inc}(t)\tau_{as}[\hat{\sigma}_1(\cos \phi \cos \theta + \sin \phi \sin \theta) + \hat{\sigma}_2(\sin \phi \cos \theta - \cos \phi \sin \theta)] \quad (10)$$

where τ_{as} is the transmission coefficient in propagating from air into the material. Since the electric field is expressed in terms of the basis for the fast and slow axes, the additional time delay for propagation through the sample and back into the air can be expressed as

$$E_{s_out}(t) = \tau_{as}\tau_{sa}[\hat{\sigma}_1 E_{inc}(t + \Delta t_{\sigma_1})(\cos \phi \cos \theta + \sin \phi \sin \theta) + \hat{\sigma}_2 E_{inc}(t + \Delta t_{\sigma_2})(\sin \phi \cos \theta - \cos \phi \sin \theta)] \quad (11)$$

where the propagation times for the two principal axes in the material are given by $\Delta t_{\sigma_1} = n_{\sigma_1}L/c_0$ and $\Delta t_{\sigma_2} = n_{\sigma_2}L/c_0$. The product $\tau_{as}\tau_{sa}$ accounts for any losses in transmission due to reflection of a portion of the terahertz pulse at the air-sample interfaces.

After propagating the terahertz pulse through the sample, one translates Eq. (11) back into the laboratory x-y frame using

$$\hat{\sigma}_1 = \hat{x} \cos \theta + \hat{y} \sin \theta \quad (12)$$

$$\hat{\sigma}_2 = -\hat{x} \sin \theta + \hat{y} \cos \theta. \quad (13)$$

Finally, the resulting electric field through the polarizer P2 is calculated by taking the dot product with the transmission axis polarization of P2 given by $\hat{P}_2 = -\hat{x} \sin \phi + \hat{y} \cos \phi$. After rearranging terms, the final electric field detected by the receiver can be expressed as

$$E_{RX}(t) = \tau_{as}\tau_{sa}[E_{inc}(t + \Delta t_{\sigma_1}) - E_{inc}(t + \Delta t_{\sigma_2})](\sin \theta \cos \theta (\cos^2 \phi - \sin^2 \phi) + \sin \phi \cos \phi (\sin^2 \theta - \cos^2 \theta)) \quad (14)$$

As a quick check, when there is no birefringence, then $\Delta t_{\sigma_1} = \Delta t_{\sigma_2}$ and the detected electric field vanishes. Likewise, if $\theta = \phi$ then the polarizers P1 and P2 are along the principal stress and birefringence axes yielding no detectable electric field since for this orientation of the sample relative to the polarizers, the birefringence does not rotate the polarization of the incident terahertz pulse.

The next step is to evaluate the difference in the two time-shifted electric fields $E_{inc}(t + \Delta t_{\sigma_1}) - E_{inc}(t + \Delta t_{\sigma_2})$. To facilitate the calculation, Fourier transforms as defined below will be utilized

$$f(v) = \int_{-\infty}^{\infty} f(t) e^{-i2\pi vt} dt \quad (15)$$

$$f(t) = \int_{-\infty}^{\infty} f(v) e^{i2\pi vt} dv. \quad (16)$$

If one assumes that the refractive indices along the principle stress directions are constant as a function of frequency, the Fourier transform of the time-shifted incident electric field may be evaluated as

$$E_{\sigma_1}(v) = \int_{-\infty}^{\infty} E_{inc}(t + \Delta t_{\sigma_1}) e^{-i2\pi vt} dt = E_{inc}(v) e^{i2\pi v \Delta t_{\sigma_1}}. \quad (17)$$

This result is expected because, in the frequency domain, the time delay is manifested as a simple multiplication by a phase factor. Using Eq. (17), the difference in the time-shifted electric fields of Eq. (14) can be evaluated as

$$E_{inc}(t + \Delta t_{\sigma_1}) - E_{inc}(t + \Delta t_{\sigma_2}) = \int_{-\infty}^{\infty} (E_{\sigma_1}(v) - E_{\sigma_2}(v)) e^{i2\pi vt} dv. \quad (18)$$

Factoring out the average phase shift on the right-hand side of the equation gives

$$E_{inc}(t + \Delta t_{\sigma_1}) - E_{inc}(t + \Delta t_{\sigma_2}) = \int_{-\infty}^{\infty} E_{inc}(v) e^{i2\pi v(\Delta t_{\sigma_2} + \Delta t_{\sigma_1})/2} \left(e^{i2\pi v(\Delta t_{\sigma_1} - \Delta t_{\sigma_2})/2} - e^{-i2\pi v(\Delta t_{\sigma_1} - \Delta t_{\sigma_2})/2} \right) e^{i2\pi vt} dv \quad (19)$$

$$= - \int_{-\infty}^{\infty} 2i E_{inc}(v) e^{i2\pi v(\Delta t_{\sigma_2} + \Delta t_{\sigma_1})/2} \sin(\pi v \Delta n L / c_0) e^{i2\pi vt} dv. \quad (20)$$

where the birefringence $\Delta n = (n_{\sigma_2} - n_{\sigma_1})L/c_0$. In the limit that the birefringence is small such that $\pi v \Delta n L / c_0 \ll 1$, the sine function can be approximated such that

$$E_{inc}(t + \Delta t_{\sigma_1}) - E_{inc}(t + \Delta t_{\sigma_2}) \simeq -2\pi i \frac{L \Delta n}{c_0} \int_{-\infty}^{\infty} v E_{inc}(v) e^{i2\pi v(\Delta t_{\sigma_2} + \Delta t_{\sigma_1})/2} e^{i2\pi vt} dv \quad (21)$$

$$\simeq - \frac{\Delta n L}{c_0} \frac{d}{dt} \left[E_{inc} \left(t + \frac{\Delta t_{\sigma_2} + \Delta t_{\sigma_1}}{2} \right) \right] = \frac{\Delta n L}{c_0} \lim_{\Delta t_0 \rightarrow 0} \left[\frac{E_{inc} \left(t + \frac{\Delta t_{\sigma_2} + \Delta t_{\sigma_1}}{2} \right) - E_{inc} \left(t + \Delta t_0 + \frac{\Delta t_{\sigma_2} + \Delta t_{\sigma_1}}{2} \right)}{\Delta t_0} \right] \quad (22)$$

where on the right-hand side of Eq. (22) the time derivative of the incident electric field pulse is approximated as a finite difference. This equation justifies the following model for the difference in the time-delayed incident pulses

$$E_{inc}(t + \Delta t_{\sigma_1}) - E_{inc}(t + \Delta t_{\sigma_2}) \simeq \Delta n A E_{diff}(t) \quad (23)$$

where Δn is the material birefringence, $E_{diff}(t) = E_{inc}(t + (\Delta t_{\sigma_2} + \Delta t_{\sigma_1})/2) - E_{inc}(t + \Delta t_0 + (\Delta t_{\sigma_2} + \Delta t_{\sigma_1})/2)$, and $A = L/c_0 \Delta t_0$ is a scaling factor. The differential electric field pulse E_{diff} can be generated mathematically by subtracting the incident electric field waveform shifted in time by Δt_0 , from the incident waveform. For simplicity, a value of $\Delta t_0 = 0.1$ ps is used which is the time interval in the terahertz waveforms digitized by the T-Ray 5000 system.

Combining Eqs. (14) and (23) gives the detected terahertz time-domain waveform as

$$E_{RX}(t) = \tau_{as} \tau_{sa} [\Delta n A E_{diff}(t)] (\sin \theta \cos \theta (\cos^2 \phi - \sin^2 \phi) + \sin \phi \cos \phi (\sin^2 \theta - \cos^2 \theta)). \quad (24)$$

The goal of the terahertz birefringence measurement is to measure the detected terahertz waveform at two different values of ϕ to determine uniquely the birefringence magnitude Δn and the stress principle stress direction θ of the material. Evaluating the measured time-domain waveform for the polarizer P1 making angles of $\phi = 0^\circ$ and $\phi = 45^\circ$ with respect to the x-axis (polarizer P2 is orthogonal to P1 for both values of ϕ) gives two equations for the measured waveforms

$$E_0(t) = \tau_{as} \tau_{sa} [\Delta n A E_{diff}(t)] (\sin \theta \cos \theta), \quad (25)$$

$$E_{45}(t) = \tau_{as} \tau_{sa} [\Delta n A E_{diff}(t)] (\sin^2 \theta - \cos^2 \theta) / 2. \quad (26)$$

By extracting the pulse amplitudes of the waveforms denoted by E_0 and E_{45} , the stress direction

$$\frac{E_0}{E_{45}} = \frac{2 \sin \theta \cos \theta}{\sin^2 \theta - \cos^2 \theta} = -\tan 2\theta \quad (27)$$

may be calculated by dividing Eqs. (25) and (26). This is the same result as derived by Kang et al. (2021).

The magnitude of the birefringence can be determined by measuring the amplitudes of the waveforms denoted by E_0 , E_{45} , and $\tau_{as} \tau_{sa} E_{diff}$. Eqs. (25) and (26) may be squared and added to yield

$$\Delta n = \frac{2c_0 \Delta t_0}{L} \sqrt{\left(\frac{E_0}{\tau_{as} \tau_{sa} E_{diff}} \right)^2 + \left(\frac{E_{45}}{\tau_{as} \tau_{sa} E_{diff}} \right)^2}. \quad (28)$$

Note that the denominator of Eq. (28) takes into account the reflective losses of the incident electric field pulse as it propagates through the air-sample interfaces. An added benefit in measuring the time shifts Δt_{σ_1} and Δt_{σ_2} referenced to no sample in the

terahertz beam path enables one to normalize out the thickness from Eq. (28). In this case the average of the time shifts may be written as

$$\frac{\Delta t_{\sigma_1} + \Delta t_{\sigma_2}}{2} = \frac{L}{c_0} \left(\left(\frac{n_{\sigma_1} + n_{\sigma_2}}{2} \right) - 1 \right) = \frac{L}{c_0} (n_{average} - 1). \quad (29)$$

Dividing Eq. (28) by Eq. (29) gives the relative birefringence as

$$\frac{\Delta n}{n_{average} - 1} = 2 \frac{\Delta t_o}{(\Delta t_{\sigma_1} + \Delta t_{\sigma_2})/2} \sqrt{\left(\frac{E_o}{\tau_{as}\tau_{sa}E_{diff}} \right)^2 + \left(\frac{E_{45}}{\tau_{as}\tau_{sa}E_{diff}} \right)^2}. \quad (30)$$

Evaluation of Eq. (30) requires measurement of the amplitudes and arrival times of the three waveforms denoted by E_o , E_{45} , and $\tau_{as}\tau_{sa}E_{diff}$.

Extraction of the stress direction from Eq. (27) and the relative birefringence from Eq. (30) requires measurement of 4 THz pulse waveforms. The time-domain waveforms through the sample with polarizers P1 and P2 oriented orthogonally as illustrated in Fig. 12 with $\phi = 0^\circ$ and $\phi = 45^\circ$ correspond to E_o and E_{45} . The measured waveform through the sample with P1 and P2 oriented parallel to each other corresponds to $\tau_{as}\tau_{sa}E_{inc}(t + (\Delta t_{\sigma_2} + \Delta t_{\sigma_1})/2)$. The waveform $\tau_{as}\tau_{sa}E_{diff}$ is calculated by shifting the waveform by one time slot (corresponding to 0.1 ps for the Teramatrix T-Ray 5000 system) and subtracting the shifted waveform from the unshifted waveform. The last required waveform is one with the sample removed which essentially measures $E_{inc}(t)$. The time delay of the waveform with the sample present compared to the sample removed effectively measures $(\Delta t_{\sigma_2} + \Delta t_{\sigma_1})/2$.

The amplitudes of the measured waveforms are calculated using a deconvolution calculation. The amplitudes and arrival times for the E_o and E_{45} waveforms are mathematically determined by a deconvolution process using Matlab software with $\tau_{as}\tau_{sa}E_{diff}$ as the reference pulse for the deconvolution. The deconvolution is performed using Fourier transforms

$$E_{deconv}(t) = A_o \text{ifft}(\text{fft}(E(t))/\text{fft}(E_{ref}(t))(\exp(-(2\pi v t_w)^2/2))) \quad (31)$$

where $E_{ref}(t)$ denotes a reference waveform. The parameter $t_w = 4$ ps represents a smoothing time window. The normalization constant A_o is chosen such that the amplitude of a deconvoluted waveform with itself (i.e., $E(t) = E_{ref}(t)$) is unity. Once the deconvoluted waveform is calculated, the amplitude A and arrival time t_a of the deconvoluted pulse is determined by fitting the peak of the waveform to a Gaussian shape $G(A, t_a, c) = A \exp(-((t - t_a)/c)^2)$. Typically, the best fit is performed on data only within ± 0.7 ps of the deconvoluted waveform peak. The arrival time $(\Delta t_{\sigma_2} + \Delta t_{\sigma_1})/2$ is calculated by deconvolving the waveform $\tau_{as}\tau_{sa}E_{inc}$ with $E_{inc}(t)$ as the reference.

As an example, a 10 mm sheet of extruded high-density polyethylene (HDPE) is characterized. Fig. 13 shows experimental measurements of the birefringence from a small piece of extruded HDPE. Fig. 13a shows the measured received electric field amplitude as a function of rotation φ for the orthogonal polarizers. Note that the theoretical fit to the experimental data is very good. The images of Fig. 13b and c show 2D maps of the local direction of the intrinsic stress in the sample as well as the measured normalized birefringence given by $\Delta n/(n_{avg} - 1)$ where Δn is the difference in refractive index along the two principle stress directions, and n_{avg} is the average refractive index of the material.

Fig. 13 (a) at a fixed point in the sample, measurement of the amplitude of the received electric field amplitude as a function of angle of rotation φ for the orthogonal polarizers. The theoretical line is from Eq. (14). (b) extracted stress angle in units of degrees from Eq. (27) and (c) normalized birefringence from Eq. (30).

Multilayer paint stacks

Terahertz NDE of multilayer paints

The analysis geometry is illustrated in Fig. 14a for an $N = 3$ layer paint stack. The terahertz pulse is incidence from air onto N dielectric layers before encountering a metallic substrate. Each layer is characterized by a thickness d_j and complex refractive index $\tilde{n}_j$. There are three basic approaches to analyzing the THz reflectivity data. The first approach is to deconvolve the reflected terahertz waveform with a reference waveform which is acquired by reflection from a perfect metal. The peaks in the deconvolved waveform represent reflections from the various material boundaries in the multilayer stack. Application of this approach is discussed in more detail in Section “Results”.

A second approach is to convert the time-domain THz waveform to the frequency domain through a Fourier transform. Analysis and extraction of the layer thicknesses and their refractive indices (both real part and imaginary part) are performed by fitting the measured reflectivity spectra to a theoretical model of multiple reflections through a multi-layer stack of layers. This method can be effective for relatively thick layers. However, as the layers become thinner, the reflected THz waveforms significantly overlap in time.

As described in van Mechelen et al. (2014), a stratified sample structure such as a paint layer stack, is difficult to analyze in the frequency domain since the reflectivity $R(\omega)$ has multiple internal reflections from the various layer boundaries. Moreover, in order to extract the refractive index by fitting the experimentally measured reflectivity to a model of the reflectivity, one would typically assume that the refractive index was real (i.e., no absorption due to the imaginary refractive index) and frequency independent. While modeling of the refractive index as primarily real and frequency independent reduces the number of fitting parameters to the experimental data, it was not a realistic description of the paint layers.

A superior method of analyzing stratified paint stack structures is to use realistic models for the frequency-dependent complex refractive index as well as fitting the theoretical model to the measured experimental data in the time-domain (van Mechelen et al., 2014; Krimi et al., 2016) rather than the frequency domain. The main benefit of the time-domain fitting is the stratified dispersive model which parameterizes each layer with a small number of fitting parameters enabling simultaneous extraction of the individual electromagnetic material parameters in multilayer structures. For application to multilayer paint structures, many dielectrics such as the polymers used in paint obey a Debye dielectric relaxation model. For this model, the frequency (ω) dependent index of refraction of the layer j material is given by

$$\tilde{n}_j(\omega) = \left(\epsilon_j^\infty + \frac{\epsilon_j^s - \epsilon_j^\infty}{1 + i\omega\tau_j} \right)^{1/2} \quad (32)$$

where ϵ_j^∞ is the permittivity at the high-frequency limit, ϵ_j^s is the static, low-frequency permittivity, and τ_j is the characteristic relaxation time of the j th paint layer. The real part of the refractive index controls the time delay of the THz pulse or equivalently the speed of the THz pulse through the material. The imaginary part of the refractive index is responsible for the absorption of the THz pulse as it propagates through a layer.

As summarized by Krimi et al. (2017), the typical analysis process involves three steps: calibration, mathematical modeling of the terahertz propagation through the multilayer structure, and optimization. In the calibration step, a reference waveform is measured by replacing the paint stack layer with a flat metallic mirror. Since the front surface of the mirror cannot be placed in exactly the same plane as the front surface of the paint stack, the analysis incorporates an overall time delay ζ between the time-domain reference and reflected pulses. The calibration step may also include terahertz measurements of individual layers of each material to extract their complex refractive indices and Debye model fitting parameters.

The modeling step mathematically propagates an input terahertz pulse waveform through the multilayer stack to calculate the resulting reflected waveform. The mathematical modeling can be typically performed first by Fourier transforming the input

Fig. 14 (a) Illustration of terahertz reflection from multilayer paint coating. The transmitter and receiver are indicated by TX and RX, respectively. Each layer is parameterized by its thickness d_j and its complex refractive index $\tilde{n}_j$. After the incident pulse waveform interacts with the paint stack, the reflected THz waveform is measured. (b) A reconstructed 3D thickness image of a two-layer sample. The presence of a defect in the coating is indicated by the red arrows.

time-domain waveform into the frequency domain. The input waveform is then propagated through the multilayer stack by an optical transfer matrix method. As an example, a Debye dielectric relaxation model can be assumed for each non-metallic paint layer. The $j = 0$ layer is assumed to be air with $n_o = 1$. The parameter N represents the number of dielectric layers such that the metal substrate is the $N + 1$ layer. In the metal substrate, various models can be used to model the metal. One option is to use a Drude model for metal for which

$$\tilde{n}_{N+1}(\omega) = \left(\frac{\varepsilon_{N+1}^\infty}{\varepsilon_o} - i \frac{\sigma_o}{\varepsilon_o \omega} \frac{1}{(1 + i\omega\tau_{N+1})} \right)^{1/2} \quad (33)$$

where σ_o is the substrate's static conductivity, and ε_o denotes the vacuum electric permittivity. If the dielectric layers and metallic layer are characterized as part of the calibration step, then the Debye parameters ε_j^∞ , ε_j^s , and τ_j as well as the metallic layer parameters, ε_{N+1}^∞ , σ_o , and τ_{N+1} are known for each layer. Alternatively, they could also be determined in the optimization step.

Given the functional form for the complex refractive indices and layer thicknesses, an incident pulse is propagated through the multilayer coating/substrate combination. One approach is to use an optical transfer matrix approach (Saleh and Teich, 1991). At each interface, it is assumed that the incident electromagnetic wave interacts at near normal incidence so that using Fresnel coefficients, the matrix representing the boundary is given by

$$P_{j,j+1}(\omega) = \frac{1}{2n_{j+1}} \begin{pmatrix} \tilde{n}_{j+1} + \tilde{n}_j & \tilde{n}_{j+1} - \tilde{n}_j \\ \tilde{n}_{j+1} - \tilde{n}_j & \tilde{n}_{j+1} + \tilde{n}_j \end{pmatrix}. \quad (34)$$

After propagating through an interface between adjacent layers, the transmitted light propagates through the thickness d_j of each layer. As the wave propagates through each layer, it experiences a frequency-dependent phase shift and is expressed through the diagonal matrix

$$D_j(\omega) = \begin{pmatrix} e^{-i\omega d_j \tilde{n}_j / c_o} & 0 \\ 0 & e^{i\omega d_j \tilde{n}_j / c_o} \end{pmatrix} \quad (35)$$

where d_j is the thickness of each optical layer, and c_o is the speed of light in a vacuum. In order to calculate the total effect, these matrices are cascaded layer by layer through the product

$$M(\omega) = \prod_{j=0}^N D_j P_{j,j+1} = \begin{pmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{pmatrix}. \quad (36)$$

The matrix Eq. (36) is known as the optical transfer matrix and completely characterizes the transmission and reflection in the multi-layered system. The reflectivity from the paint stack is calculated using the optical transfer matrix from

$$R(\omega) = \frac{M_{21}(\omega)}{M_{11}(\omega)}. \quad (37)$$

Lastly, there is an optimization step in which the thicknesses of the various layers are optimized in order to minimize the error between the measured time-domain reflected waveform and the waveform predicted by the mathematical modeling. The time-domain reflected electric field from an N -layer paint coating may be expressed as

$$E_R(t) = \mathcal{F}^{-1} [e^{-2\pi i \xi} R(\omega) \mathcal{F}[E_I(t)]] \quad (38)$$

where $\mathcal{F}[E_I(t)]$ is the Fourier transform of the incident Terahertz pulse. The analysis incorporates an overall time-delay ξ between the time-domain reference and reflected pulses. If the Debye model parameters for each layer have not been determined in the calibration step, they could be determined in the optimization step. Multiplying the Fourier Transform of the incident electric field by the reflectivity Eq. (37) and the overall phase shift effectively accounts for the propagation of the THz pulse through the various layers of the paint layer stack. The inverse Fourier transform converts the frequency-domain back into a time-domain pulse. The time-domain reflected pulse depends on the refractive indices and thicknesses of each paint layer, the reflectivity of the metallic substrate, and the overall time delay ξ .

Extraction of best-fit parameters is accomplished using a minimization algorithm to optimize the fitting parameters by minimizing the difference in the measured terahertz waveform compared to the waveform generated from Eq. (38) with the fitting parameters. As an example, a least-squares fitting process could be used as outlined below. To this end, let m be the number of fitting parameters. For example, with a two-layer model there are 2 paint layer thicknesses, there are 6 Debye parameters for the paint layers, 3 Drude parameters for the metal substrate, and an overall time delay for a total of $m = 12$ parameters. The measured data $E_{data}(t)$ is defined over some time window $[0, T]$. While the maximum value of $T = 160$ ps could be used since the Tray 5000 THz instrumentation used in this project records a 160 ps window of data, the time window is restricted to a 65 ps window centered on the main structure of the terahertz pulse (Fig. 15). The computational problem can be expressed as minimizing the squares of the error between the measured and fitted time-domain data. More precisely,

Fig. 15 Comparison of experimental reflected terahertz waveform (blue) to theoretical fit (red) using a two layer model.

$$\min_{\vec{P} \in \mathbb{R}^m} \text{Error} = \min_{\vec{P} \in \mathbb{R}^m} \left[\frac{1}{2} \left\| E_{data}(t) - E_R(\vec{P}, t) \right\|_{L^2([0, T])}^2 \right] \quad (39)$$

where $\vec{P}$ is a vector storing the m fitting parameters, and the fitting parameters must be part of a physically realizable parameter space (for example the thicknesses must be positive values). The norm defining the error is given by

$$\| \cdot \|_{L^2([0, T])} = \left(\int_0^T | \cdot |^2 dt \right)^{1/2}, \quad (40)$$

and $E_R(\vec{P}, t)$ is the parameter-dependent electric field computed in the frequency domain and mapped back to the time-domain through Eq. (38). The norm of the difference $E_{data}(t) - E_R(\vec{P}, t)$ measures the misfit, over the time-domain $[0, T]$, between the experimentally obtained data and the reflected electric field. The integration required by the norm is computed numerically via the trapezoidal rule.

As an example of the quality of the fit, Fig. 15 shows the experimentally measured and fitted electric field for a two-layer paint stack consisting of a UV topcoat, rain erosion layer, and metallic substrate (assumed to be a perfect metal). This data represents one pixel on a 2D painted sample. By recording the terahertz reflected waveforms on a pixel-by-pixel basis, refractive index and layer thickness maps similar to those in Fig. 14b may be extracted from the terahertz imaging data.

In adapting the terahertz pulsed imaging technique to real-time evaluation of paints, attention must be given to rapid processing of the images and reducing the computational time of the minimization algorithm. Krimi et al. (2017) have shown that utilizing Rouard's method (Krimi et al., 2016) rather than an optical transfer matrix approach enables one to reduce the computational time by a factor of 1.7 and the graphics processing unit (GPU) allocated memory by a factor of about 2.3. The methodology of (Krimi et al., 2017) utilizes a genetic algorithm optimization rather than a least squares optimization to provide best-fit parameters. This approach enables resolution of individual layer thicknesses of typically 7 μm with an absolute accuracy of less than 1 μm . Terahertz nondestructive monitoring of automobile multilayer paints has in fact been implemented on a limited scale in industrial automobile factories (<https://das-nano.com/success-story/volkswagen/>).

Terahertz NDE of paint corrosion

While terahertz pulse imaging has been adapted for industrial quality control measurements of paint layer thicknesses, another application of the methodology is detection of underlying corrosion of multilayer structures. To a large extent, the same terahertz instrumentation and methodology which was developed to assess the fabrication of multilayer structures can be used to assess the structure's degradation due to corrosion. An early example is the characterization of corrosion under Space Shuttle tiles which used the same instrumentation which was developed to inspect sprayed-on foam insulation (Anastasi et al., 2007).

Several studies demonstrating the feasibility of corrosion detection by terahertz imaging have been reported. As an example, one study (Tu et al., 2021) created buried corrosion layers by painting over rusted areas to create a 'hidden' corrosion defect. By comparing the terahertz pulse shape where no rust was present compared to a rusted area under the paint, it was readily observable that the terahertz pulse shape was significantly changed by the presence of rust. Changes in terahertz pulse shape were also present for which adjacent paint layers separated and also when the coating became detached from the substrate (some reports refer to the detachment of the coating from the substrate as 'blistering'). The change in pulse shape due to delamination of different

coating layers can be easily understood due to the presence of additional material boundaries which partially reflect the propagating terahertz radiation as well as additional time delays between pulse peaks as the spatial separation between layers increases (Dong et al., 2017).

Using a similar sample fabrication method, (Fuse et al., 2012) tested the viability of rust detection hidden under epoxy using carbon steel plates as substrates. Rusted areas on the substrate were created by placing a few drops of salt solution on its surface. After wiping off the residual solution, epoxy resin was used to cover the substrate surface. Terahertz reflection measurements showed that the rust strongly attenuates the terahertz radiation compared to uncorroded metal enabling sufficient contrast in terahertz pulsed imaging reflection measurements to detect the presence of the buried rust.

In a follow-up paper (Fuse et al., 2016), the technique was extended to higher terahertz frequencies using a quantum cascade laser (QCL) as the terahertz source and a terahertz camera for detection. Samples were exposed to a coastal environment for 27 months. The buried substrate surface corrosion resulted in an increase in surface roughness which increased the scattering, resulting in a concomitant decrease in the terahertz reflectivity. In comparing the QCL detection system to the THz TDS system, the QCL system was more effective in detecting early onset of corrosion since the rust resulting from γ -FeO(OH) exhibits absorption peaks at around 6.6 THz and 9.3 THz whose tails spectrally overlap the frequency range of the QCL. The authors report that the absorption coefficient for 2.5 THz waves (QCL) is about 40 times higher as compared to the ~ 0.3 THz waves which are employed in THz-TDS thereby enabling detection using the QCL system of even small amounts of corrosion with corresponding relatively weak terahertz absorption.

In developing terahertz nondestructive evaluation to evaluate the degradation of multilayer paint stacks with aging, it is important to consider what aspects of the paint layer properties that are probed by terahertz waves might change with coating degradation. Clearly, if the dielectric paint layers are degraded, this might be manifested either in changing layer thicknesses or in the Debye model permittivity. In addition, chemical corrosion of a metallic substrate or layer, as discussed above, creates a rough surface that increasingly scatters terahertz radiation with corrosion. Changes in these parameters will alter not only the amplitudes but also the timings of the reflected pulses from each layer in the paint stack resulting in a change in the overall reflected THz-TD waveform as well as the deconvoluted waveform.

The reflectivity of a rough metallic surface can be modeled using the Beckmann and Spizzichino model (Beckmann and Spizzichino, 1987; Cacciari and Siano, 2017). Using this model, the mean power (i.e., square amplitude of electric field) in the specular reflected direction may be written as

$$P_s = e^{-g} \left(1 + \frac{\tau_L \sqrt{\pi}}{2D} \sum_{m=1}^{\infty} \frac{g^m}{m! \sqrt{m}} \right) \quad (41)$$

where

$$\sqrt{g} = 4\pi \frac{R_q v}{c_0}, \quad (42)$$

D is the terahertz beam spot size, R_q is the standard deviation of the normally distributed heights of the rough surface, τ_L is the correlation distance, c_0 is the speed of light in a vacuum, and v is the terahertz frequency. When $R_q = 0$, corresponding to a flat metallic surface with no surface roughness, Eq. (41) reduces to unity indicating perfect reflection from a flat metal surface. When the surface roughness is present, the power in the specular reflected direction is reduced with increasing roughness since the rough surface scatters some of the terahertz power into non-specular directions. In the limit of small roughness $g \ll 1$, the power P_s can be shown to approximately depend quadratically on the terahertz frequency

$$P_s \simeq 1 - \left(\frac{4\pi R_q v}{c_0} \right)^2 \left(1 - \frac{\tau_L \sqrt{\pi}}{2D} \right). \quad (43)$$

If the terahertz source is a broad-banded pulse source, such as with terahertz time-domain spectroscopy, the spot size D of the focused pulse depends on the terahertz frequency. Assuming a terahertz Gaussian beam with initial diameter D_f which is focused to a spot size D using a lens of focal length f , the spot size at the focus can be approximated as $D = c_0 f / \pi D_f v$. In this case, the power P_s becomes

$$P_s \simeq 1 - \left(\frac{4\pi R_q v}{c_0} \right)^2 \left(1 - \frac{\tau_L \pi^{3/2} D_f v}{2c_0 f} \right). \quad (44)$$

Accelerated corrosion protocols

Many of the published studies of terahertz nondestructive evaluation of buried corrosion layers, such as those cited above, did not follow any established protocol for accelerated corrosion testing of samples. Their emphasis was to establish the prospect of terahertz NDE of buried corrosion. In the rest of this section, terahertz NDE of multilayer paint samples is described in which the samples were exposed to an accelerated corrosion test method (Dante, 2019). The samples are periodically removed from the accelerated corrosion chamber to characterize the corroded samples using terahertz NDE.

The accelerated corrosion methodology combines cycling of dry and wet environmental conditions with ‘aggressive’—meaning higher salt concentration and higher acidity ($\text{pH} < 5$)—salt-fog solutions. For the work presented in this section, the accelerated corrosion test method of Dante (2019) was adopted. The core components of the corrosion solution are seawater as detailed in Table 2. As described by Dante, nitrate is added because all coastal sites from which they acquired chemical samples showed nitrate. Moreover, the nitrate solution is realistic since it is also an important oxidizer in atmospheric chemistry. The low pH is the result of sea salt aerosols (around $1\ \mu\text{m}$) exhibiting pH values of approximately 3. Due to the low pH in the solution, the saltwater solution is only applied via fog for 6 h twice a week. Subsequent to fog exposure, the relative humidity is cycled for either 3 or 4 days until the next salt fog exposure. The relative humidity cycling is performed at $40\ ^\circ\text{C}$; the samples spend 2 h at 90% RH 3 h at 65% RH and 1 h at 40% RH. This cycle repeats until the next fog exposure with a total of two fog exposures in a 1 week period.

The multilayer paint samples, illustrated in Fig. 17a consisted of an aluminum substrate, primer layer (approximately 0.7 mils thick), conductive layer (approximately 1.1 mils thick), a second primer layer, rain erosion layer (approximately 10 mils), and an ultraviolet blocking topcoat layer (approximately 1.7 mils). The tested coupons (roughly 3 in. by 3 in.), were cut from larger painted panels. These cuts made the edges of the samples vulnerable to the solution seeping in through the side of the sample as opposed to through the topcoat layer, so the edges of the samples were covered with waterproof tape.

On a weekly basis, just prior to exposure in the salt fog chamber, the multilayer paint samples are removed from the humidity chamber for THz-TD testing. Prior to testing, the samples are rinsed with deionized water and blown dry with air to remove any surface build-up of salt deposits. The surface salt deposits are removed so that their presence on the surface does not lead to any artifacts in the terahertz waveform due to scattering from the deposits. Experiments have shown that the subsequent 6 h exposure to salt fog will fully saturate the coating for the next humidity cycle. To eliminate potential contribution of water absorbed into the paint layers to the measured terahertz waveform, prior to terahertz characterization the samples are dried in a constant flow of $50\ ^\circ\text{C}$ dry air for 1 h. Time-domain waveforms and images were acquired using a Teramatrix T-Ray 5000 THz time-domain system.

Results

By measuring the amplitude of the reflected terahertz radiation within a fixed frequency band, one can easily generate images of the corrosion progression as shown in Fig. 16. The frequency-dependent reflectivity is calculated by dividing the reflected frequency-dependent magnitude by the frequency spectrum of a reference pulse which was reflected from a flat metal plate. The average reflectance within a specific frequency band is then calculated for each pixel. The upper left image is recorded from the sample prior to any accelerated corrosion. The darker gray lines near the boundary of the sample represent the edges of the tape on the samples. Note that prior to accelerated corrosion (upper left image) that the reflectivity of the sample is very uniform across the sample. As the sample undergoes accelerated corrosion, the reflectivity decreases near the corners and edges of the sample where the salt-fog is able (a) to penetrate through gaps in the tape or (b) effectively collect under the tape near the sample edges.

In addition to the time-domain analysis described above in which the permittivity of each layer is assumed to obey a Debye relaxation model (Eq. 32), the reflected terahertz waveform may also be analyzed using a deconvoluted pulse approach. In its simplest form, the deconvoluted pulses represent the partial reflection of terahertz radiation from each boundary in the multilayer paint stack. The deconvolution analysis enables one to determine the amplitude as well as the arrival time from each partial reflection. The advantage of this simplified approach compared to the time-domain analysis in Section “Terahertz NDE of multilayer paints” is that one does not need to assume any particular functional form (i.e., Debye relaxation model) for the paint layer permittivity.

A typical terahertz time-domain reflected waveform from an undegraded sample and the corresponding deconvoluted waveform which is calculated using the Tray 5000 software is shown in Fig. 17b. The deconvolution algorithm uses a reference waveform which is acquired by replacing the sample with a flat metallic plate. The deconvolution waveform shows four main peaks. Peak 1 is the front reflection from the air-top coat boundary. Peak 2 is the reflection from the top coat/rain erosion boundary. Peak 3 is a reflection from the aluminum substrate. Peak 4 is due to multiple reflections between the front surface of the coating and the aluminum substrate. The refractive index of the rain erosion layer is similar to that of the thin primer layer such that there is no observable reflection from the rain erosion/primer boundary.

A simple analytical method to determine if the multilayer paint stack is changing with corrosion is to analyze the arrival times and amplitudes of the deconvoluted pulses. For this analysis method, assumptions of particular models for the dielectric layers (i.e., Debye) nor metallic substrate (e.g., Drude) are not required. As an example, the time delay between the deconvolved pulse 2 and 1 is a measure of the optical path length (i.e., real refractive index multiplied by the thickness) of the topcoat layer while the time delay

Table 2 Composition of modified sea salt solution for corrosion testing.

Modified Sea Salt Solution with Nitrate Ions	
NaCl	$22.26\ \text{g L}^{-1}$
$\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$	$11.10\ \text{g L}^{-1}$
Na_2SO_4	$4.00\ \text{g L}^{-1}$
NaNO_3	$3.27\ \text{g L}^{-1}$
HCl (1 N)	(1 mL)

Fig. 16 Time sequence of terahertz images taken at weekly intervals during accelerated aging. The images correspond to the average measured reflectivity of the terahertz waveform in the 0.5–1 THz range. Top left image was acquired prior to aging. The presence of tape on the edges of the sample is evident in the images as well as the onset of corrosion from the edges of the sample.

Fig. 17 (a) Schematic of multilayer paint samples. (b) Typical reflected terahertz waveform (solid black, left axis) and deconvolved waveform (dashed gray, right axis) from center pixel location of the sample. Main peaks of the deconvolved waveform are labeled from 1 to 4.

Fig. 18 (a) Measured time-of-flight between pulses 2 and 1 (diamond), 3 and 1 (square), and 4 and 1 (circle) as a function of number of weeks of corrosion. (b) Deconvolved amplitudes of pulses 1 (diamond), 2 (square), 3 (circle), and 4 (open circle) as a function of weeks of corrosion. Data is taken from a pixel at the center of the sample.

between pulse 3 and 2 is a measure of the optical path length of the rain erosion layer. Fig. 18a shows the measured time of flight between the various pulses as measured from the center of the sample. Note that the pulse time-of-flight relative to the front reflection from the center of the paint layer stack does not significantly change during the corrosion process. Likewise, the amplitudes of the various deconvolved pulses (Fig. 18b) show essentially no change with accelerated corrosion. This suggests that the salt-fog corrosion degradation through the coating is a very slow process compared to corrosion through edges of the sample. Even after 14 weeks of degradation, the 'shine' of the topcoat layer as measured by visible light illumination is still present. Consequently, one may conclude that for the accelerated corrosion protocol used in this study, the Debye permittivity function and thicknesses of the dielectric layers are not degraded.

This result is consistent with the functioning of the UV-rain erosion layers. These layers are hydrophobic and tend to repulse the acidic salt fog. However, at the edges of the sample, the acidic salt fog is in contact with the metallic substrate under the paint layers. Consequently, the corrosion of the metallic layer through the edges of the sample is a much faster process than the comparably slow degradation through the UV-rain erosion layers.

The progress of the corrosion from the edges of the sample under the tape and inward towards the center of the sample is evidenced by the changing reflectance with increasing weeks of corrosion. The mechanism by which the reflectivity decreases is twofold: For the first step, the corrosion leads to an increase in roughness of the aluminum substrate which more efficiently scatters incident terahertz radiation. The second mechanism is a 'bulging' or 'blistering' of the multilayer paint stack as the corrosion continues and the paint layer stack detaches from the substrate. As shown in the visible image of the sample (bottom right panel of Fig. 16) after 14 weeks of corrosion, the chemical corrosion lifts the paint stack from the sample. Moreover, visible images of the edges of the sample confirm the failure of the primer layer and detachment of the rain erosion layer from the substrate surface.

After the edges of the sample corrode, the multilayer paint stack detaches from the substrate as shown by the visible images in Fig. 19. The topcoat appears white with a shiny finish. The thickest layer is the rain erosion layer which appears black in visible light. Visual inspection shows that for the triangular section of Fig. 19b for which the rain erosion layer (black in color) has completely detached from the substrate, the primer layers have failed: there are locations where no primer is still attached to the rain erosion layer. In other areas, the primer still remains attached to the rain erosion layer, but the bottom primer/metallic layers are no longer intact. Probing of the detached area with an ohmmeter indicates no electrical conductivity meaning that the metallic layer between the two primer layers has been rendered highly resistive.

By analyzing the arrival times and amplitudes of the deconvolved waveforms, one can observe the progression of the corrosion in time. Fig. 20 shows the measured amplitude of the deconvolved pulse amplitudes as measured at the point indicated by the white arrow in Fig. 16. Prior to 7 weeks of degradation, the amplitudes of the pulses are essentially unchanged. However, in week 8 begins a reduction in the magnitude of all four pulses indicating the progression of corrosion to that point on the sample.

It is interesting to note that while the deconvolved amplitudes show evidence of corrosion at 8 weeks, the time-of-flight measurements do not show any significant change until 12 weeks. The unchanging time-of-flight values indicate that the multilayer stack from the top coat/rain erosion layer/primer layer/metallic layer remains intact during the early stages of corrosion. Examination of the deconvolved pulses suggests that the four peaks of Fig. 17b remain at fixed relative positions even as the substrate roughens during corrosion. In this scenario, the detachment of the paint layer primarily occurs at the primer/ substrate boundary.

While Fig. 16 clearly shows the progression of corrosion under the multilayer paint stack with aging, the regions of reduced terahertz reflectivity very closely follow regions of bulging which are readily apparent in the visible images. Does terahertz NDE reveal the presence of corrosion before the effects of the corrosion are visibly apparent on the surface? To answer this question, one needs to separate the two contrast mechanisms for detection of corrosion: (a) increased surface roughness of the metal due to chemical corrosion (b) followed by bulging of the surface due to detachment of the multilayer paint stack from the substrate. The roughening of the metallic layer precedes and ultimately causes the detachment of the multilayer paint stack from the substrate.

Fig. 19 Visible images of a corroded sample after 15 weeks. (a) top view of the corroded sample. (b) close up of the same sample with detached portion of coating cut away.

Fig. 20 Measured (a) pulse time-of-flight and (b) deconvolved amplitude at pixel ($x = 15$, $y = 13$). This pixel is denote by the white arrow. Notation for symbols is the same as Fig. 18.

The bulging leads to a reduction in the detected reflected terahertz power since the tilt of the bulging surface directs some terahertz power away from the terahertz receiver.

The topology (and bulging) of the front surface of the paint stack can be extracted from the terahertz data by plotting the arrival time of the deconvolved pulse from the front surface reflection (i.e., air-top coat boundary) of the paint stack. The local height of the bulge can be calculated by measuring the time difference of pulse Δt reflected from a region of the sample where no bulge is present and a location where the bulge is present. The height of the bulge is simply given by $c_0 \Delta t / 2$.

Fig. 21a shows a higher resolution (0.2 mm pixel size) reflectivity image of a small portion of the sample after 15 weeks of corrosion. A horizontal slice of data, as indicated by the black line, is analyzed to extract the surface height and Peak 3 amplitude. The dashed line in Fig. 21b indicates the location where the surface height begins to increase indicating the edge of the bulging blister as the pixel position moves from right to left towards the bulging paint surface. At larger pixel positions (~ 72 – 80), the bulging is preceded by a reduction in the peak 3 amplitude as a result of increased surface roughness due to corrosion. A measurable reduction with accelerated corrosion in the amplitude of the 3rd deconvolved pulse from the metallic layer may be an early indicator that the entire stack will soon detach from the substrate creating a bulge (i.e., blister) on the surface.

Regions of increased substrate roughness due to corrosion may also be visualized using polarized light reflection. Monte Carlo modeling of terahertz propagation and reflection from rough surfaces (Xie et al., 2022) show that roughening of the metallic surface leads to a randomization of the polarization direction of the reflected radiation. As an example, (Xie et al., 2022) shows significant cross-polarization scattering for radiation with a terahertz wavelength of 0.3 mm when the RMS surface roughness R_s becomes 0.5 mm and the correlation length τ decreases to 5 mm. The T-Ray 5000 transmitter and receiver modules are polarization sensitive. Cross-polarization images are acquired by orienting the polarization axes of the transmitter and receiver modules so that they are orthogonal. With this cross-polarization orientation, only reflected radiation that has been scattered into the cross-polarization orientation will be detected. Fig. 22 highlights areas of the sample which surround the bulge in the paint layers. The area immediately surrounding the bulge represents regions of the metallic layer which has been roughened by corrosion.

Fig. 21 (a) High resolution Terahertz reflectivity image (arbitrary units) in the 0.5–1 THz frequency band of a 20 mm by 20 mm section of sample showing a bulging blister on the paint layer surface. (b) The surface height and peak 3 amplitude as measured along a horizontal slice as indicated by the black horizontal line in (a). The dashed line indicates the location where the surface height begins to increase indicating the edge of the bulging blister. At higher pixel positions, the bulging is preceded by a reduction in the peak 3 amplitude as a result of increased surface roughness due to corrosion.

Fig. 22 Cross polarization image (0.2 mm pixel size) measuring total power (unnormalized) in 0.5–1 THz band. Green outline indicates boundary—as determined by the time arrival of the front surface reflection (pulse 1) from the paint layer stack—that is bulging at least 30 μm . Brighter portions of the image surrounding edge of bulge (indicated by black arrows) indicate regions of enhanced scattering due to surface roughness from corrosion.

Conclusion

In its current strategy, the DoD defines the number one barrier to moving AM into the realm of accepted manufacturing technologies as “rapid and standardized approaches for qualification of materials and processes, and certification of AM parts.” Terahertz nondestructive evaluation techniques could play a major role in the creation of a standardized qualification process for additively manufactured components. This chapter has showcased the current use of THz NDE on two emerging material applications: additively manufactured components and multilayer paint stacks. For the first application, NDE of fused deposition modeling (FDM) printed plastics and nanoparticle jetted ceramics were emphasized. These examples represent an initial utilization of this technology for AM. As new materials for AM are developed and new printing techniques are created, the requirement to standardize approaches for rapid qualification of materials and processes will be unchanged. THz NDE can and should be applied to aid in the maturing process of this technology, whether it is using it for defect detection, creating full 3D reconstructions, or measuring a material’s electromagnetic properties as just a few prime examples.

Aside from terahertz optical components, THz NDE of additively manufactured components can detect defects in the 3D printed structures which could significantly impact their functionality. Simple examples include cracks/voids in the printed structure and regions of high mechanical stress. A complete 3D image of an AM part could enable detailed comparison of design versus printed dimensions, structural defects, etc. THz CT of AM parts has many of the same analysis capabilities as X-ray CT: detection of internal voids and defects, measure internal and external geometry, and ability to compare printed parts to their CAD design. A significant challenge to the implementation of THz CT is refraction of the THz rays by the sample. Corrections to THz CT analysis to account for Gaussian beam propagation as well as refractive effects (using SART, ART, etc.) have been demonstrated.

Owing to refractive effects, THz NDE is best suited to planar structures. Examples include the material characterization and thickness measurements of multilayer paint stacks. Adapting THz NDE to corrosion detection shows that the methodology has sufficient sensitivity for early detection of failures due to corrosion in multilayer paint structures. Based on the accelerated corrosion

studies using salt-fog exposure and humidity cycling, a 5.6% change in the reflectivity from the metallic layer indicates significant chemical corrosion of the multilayer paint coating prior to any visible evidence of a blister on the coating surface. Further chemical corrosion (and commensurate decrease in terahertz reflectivity) leads to detachment of the coating from the substrate.

The major driving force behind the development of additively manufactured terahertz and microwave components is the development of next-generation wireless communication systems. Some of the currently used polymers for the manufacturing of terahertz optical components include high-density polyethylene (HDPE), polypropylene, polystyrene, and TOPAS. Most of these polymers exhibit relatively minimal attenuation, but also have refractive indices close to 1.5. Several research teams have succeeded in creating by 3D printing various THz quasi-optical devices including GRIN lenses, topological waveplates, phase plates, polarization splitters, q-plates, and stepped-refractive-index lenses.

Acknowledgments

The authors gratefully thank P. Parsons and M. Mirotznik for the ceramic samples and microwave measurements described in this chapter. The amber samples used in this study were provided by P. Barden. The authors gratefully acknowledge the support of the Strategic Environmental Research and Development Program (SERDP) and US Army Combat Capabilities Development Command (CCDC) Armaments Center, Picatinny Arsenal.

Abstract

We discuss the electronic and optical properties of various semiconductor nanostructures: nanocrystals, nanorods, nanowires and nanoplatelets. The modification of the shapes of these structures leads to very different energy spectra and different densities of carrier states. We show that the optical properties of all these structures are controlled by excitons. Optical properties are also strongly affected by the large difference in dielectric constants of the semiconductor and the matrix in which the nanostructures are embedded. This phenomenon leads to the dielectric confinement effect that increases the energies of the electron and hole confined levels and, due to the small dielectric constant of the matrix, increases the exciton binding energy by up to 0.5 eV in the thinnest nanoplatelets. In the end, we discuss the exciton fine structures created by electron-hole spin-spin exchange interaction enhanced by the spatial confinement of carriers in nanoscale semiconductors. This fine structure, consisting of the dark (optically passive) and bright (optical active) exciton sublevels, strongly affects photoluminescence and polarization properties in various nanostructures.

Glossary

Exciton Electron-hole pair bound by Coulomb attraction.

Semiconductor Extended solid with a non-conductive gap in the band structure.

Nanocrystal (NC) A large molecule in which the core atoms are organized in the crystal structure of the corresponding bulk compound.

Quantum size effect Energy increase of an electrical carrier due to confinement in a small crystal volume.

Nanocrystal characterized by a 3D confinement potential for carriers resulting in a discrete energy spectrum **Nanorod (NR)** Semiconductor nanocrystal that has strongly elongated ellipsoidal shape.

Nanoplatelet (NPL) Semiconductor nanocrystal, that has shape of two dimensional large size flakes.

Key points

- Four basic nanoscale semiconductor structures are introduced: spherical nanocrystals, nanorods, nanoplatelets and nanowires.
- Spatial confinement of carriers and the density of states in these four basic structures is discussed.
- Size dependence of the optical properties of spherical nanocrystals is considered.
- Effect of dielectric confinement on electron-hole energy spectra in anisotropic semiconductor nanostructures is discussed.
- Two-dimensional excitons control optical properties of nanoplatelets.
- One-dimensional excitons control optical properties of nanorods and nanowires.
- The exciton fine structure created by the electron-hole exchange interaction enhanced by spatial confinement explains the photoluminescence properties of nanostructures.

Introduction

There are four basic chemically synthesized, nano-scale semiconductor structures: spherical nanocrystals (NCs), nanorods (NRs), nanoplatelets (NPLs), and nanowires. Transition electron microscopy (TEM) images of these nanostructures are shown in Fig. 1. The TEM image of a bare CdSe NC and its atomistic structure in Fig. 1A show that the nanocrystal is just a big molecule with its atoms organized in a bulk crystal structure (see Fig. 1B). Current technology allows us to vary the size of these NCs in a controlled manner from 1 to 100 nm. Semiconductor NCs are the most heavily studied of the nano-scale semiconductors. The size dependence of NC optical properties was discovered independently in two different materials: in semiconductor-doped glasses by Ekimov and Onushchenko (1981) and in aqueous solutions by Brus (1983). After more than 40 years of research, we have a solid theoretical basis that allows us to understand most of the electronic, optical, and transport properties of NCs.

Current technology allows for the growth of strongly elongated NCs that have ellipsoidal shape; so called NRs. The TEM image of the CdSe NRs grown by Peng et al. (2000), is shown in Fig. 1D. Even more unexpectedly, current technology allows for the growth of NCs that have the shape of freestanding, two-dimensional semiconductor sheets, in which thickness can be changed from 2 to 7 monolayers. These nanostructures are called nanoplatelets (NPLs) and a TEM image of three monolayer thick CdSe NPLs is shown in Fig. 1C (Ithurria et al., 2011). Nanometer thick crystals that can be several millimeters long are grown today. They are called nanowires, and a TEM image of CsPbBr₃ nanowires is shown in Fig. 1E (Folie et al., 2020).

Scientists have grown various modification of these four basic structures. Today, they are typically complex core-multishell heterostructures, often with chemically functionalized surfaces. These were created to satisfy specific engineered properties, that can include the frequency of light emission, ability to transfer photoexcited electrons, suppression of nonradiative recombination,

Fig. 1 Transmission electron microscopy (TEM) images of four basic nanostructures. A—TEM image of 5 nm radius spherical CdSe nanocrystal (NC). B—atomistic structure of 5 nm radius CdSe NC. shortening of the radiative decay time, doping, and/or specific solubility in various environments. The most important of these modifications are the core/shell heterostructures that prevent optically excited carriers from escaping to the nanostructure surface and increase the photoluminescence (PL) quantum yield (Hines and Guyot-Sionnest, 1996).

Recent advances in the fabrication, physical understanding, and application of chemically synthesized nanoscale semiconductors, such as spherical NCs, NRs, NPLs and nanowires, have been driven by intense interest in their unusual and potentially useful electronic and optical properties. A wide class of semiconductors, such as covalent Si and Ge, III-V group compounds such as GaAs, InAs, GaP, InP; II-VI group compounds, such as CdSe, CdS, CdTe, ZnSe, PbS, PbSe, HgTe; I-VII group compounds such as CuCl, CuBr, AgBr semiconductors, and perovskites can be prepared today in nanoscale form (Efros and Brus, 2021). Size- and shape-controlled tunability of their electronic, optical, and transport properties (see Fig. 2, that shows size-tunable absorption and PL of CdSe NC, Efros et al., 1996, where the spectral colors reflect the color of emission line) combined with the ability to chemically and physically manipulate these “free-standing” nanostructures with nanometer precision, open exciting new opportunities for the development of novel functional materials with a wide range of applications. Such materials allow “bottom up” chemical approaches for assembly.

Nanoscale semiconductors can be positioned and assembled into two-dimensional and three-dimensional artificial super “crystals,” custom-designed nanocrystal “molecules,” and functional nanocrystal-biomolecular conjugates. Thus, multiple applications of their fundamental properties to real-world devices is closer than ever. Research into nanocrystals has been already translated into the production of commercial devices. In May 2011, the company Nanosys announced a product called the Quantum Dot Enhancement Film 6. This is a thin layer of nanocrystal quantum dots (QDs) that convert the blue light of a GaN light-emitting diode into bright colors which can be used in liquid-crystal displays. Around the same time, Samsung announced the creation of a 4-inch quantum-dot-based color display, with higher definition and lower power consumption than commercial liquid-crystal displays. Today, the production of quantum dot TVs is a \$3 billion business for the Samsung corporation.

Spatial confinement of carriers in nanoscale semiconductor structures

The significant blue shift of band-edge optical transitions, and the corresponding increase of the optical energy gap up to 1 eV, which is seen in CdSe NCs with decreasing NC size (shown in Fig. 2) is connected with the spatial confinement of carriers. This increase of the optical gap is even larger in lead chalcogenide NCs and CdSe nanoplatelets and nanorods (Efros and Brus, 2021). The spatial confinement of the carriers depends on the geometry of the nanoscale semiconductor structures. In a parabolic band approximation, each electron and hole state in spherical NCs is characterized by angular momentum, l . The energy of the corresponding confinement levels in this zero-dimensional structures (0D): (Efros and Efros, 1982)

$$E_{e,h}^{0D}(l, n) = \frac{\hbar^2 \varphi_{l,n}^2}{2m_{e,h}a^2} \quad (1)$$

is inversely proportional to the effective mass of electrons, m_e , and holes, m_h , and the square of the NC radius a . $\varphi_{l,n}$ are n -th, the roots of the spherical Bessel function of index l ($l = 0, 1, 2, \dots$). The lowest roots are: $\varphi_{0,1} = \pi$, $\varphi_{1,1} \approx 4.49$, $\varphi_{2,1} \approx 5.76$ and $\varphi_{0,2} = 2\pi$. Adopting the notation from atomic physics, the levels with angular momentum 0, 1, and 2... are called S, P, and D.

The electronic properties of NPLs are very similar to those of semiconductor quantum wells. The motion of carriers in the NPL plane is almost free, but they are strongly confined in the perpendicular direction. This confinement type leads to the formation of numerous two-dimensional (2D) electron and hole subbands, the bottom of which is described as

$$E_{e,h}^{2D}(N) = \frac{\hbar^2 \pi^2 N^2}{2m_{e,h}L^2}, \quad (2)$$

where L is the thickness of the NPL, and N is the subband number ($N = 1, 2, 3, \dots$).

In nanowires, carrier motion is free along the nanowire axis and is strongly confined in the perpendicular directions. This confinement type leads to the formation of numerous one-dimensional (1D) electron and hole subbands. In cylindrical-shape nanowires, the bottom of such 1D subbands are described as:

$$E_{e,h}^{1D}(l_z, n) = \frac{\hbar^2 \varphi_{l_z,n}^2}{2m_{e,h}\rho^2}, \quad (3)$$

where ρ is the nanowire radius, and $\varphi_{l_z,n}$ are the n -th roots of Bessel functions of integer index l_z : $J_{l_z}(\varphi_{l_z}) = 0$ ($l_z = 0, \pm 1, \pm 2, \dots$). The lowest roots are: $\varphi_{0,1} \approx 2.40$, $\varphi_{1,1} \approx 3.83$, $\varphi_{2,1} \approx 5.14$ and $\varphi_{0,2} \approx 5.52$. Adopting the notation from atomic physics, the levels with angular momentum 0, 1, and 2... are called Σ , Π , and Δ (Shabaev and Efros, 2004).

All nanoscale semiconductor structures are low dimension structures—for which carrier spectra are usually characterized by the density of states;

$$\rho(\varepsilon) = \sum_{\varepsilon-\Delta\varepsilon}^{\varepsilon+\Delta\varepsilon} N_i, \quad (4)$$

which is the number of states, N_i , in the small energy interval $\Delta\varepsilon$. In 3D, 2D, and 1D structures, where carriers have the opportunity to move freely in at least one dimension, the density of states is quasi-continuous as you can see in Fig. 3. For structures with different dimensionality, D , the density of states can be written as

$$\rho(\varepsilon) \sim (\varepsilon - E^D)^{(D-2)/2}, \quad (5)$$

where E^D is the bottom of the corresponding subband.

One can see from Eq. (5) that in bulk, $D = 3$, the density of states is proportional $\sim \sqrt{\varepsilon}$. In NPLs and quantum wells, the density of states has the form of a sum of steps starting at the positions of quantum-confined levels described in Eq. (2) (see Fig. 3B). In one-dimensional structures like nanowires, $D = 1$, the density of states consists of sharp, asymmetric peaks (see Fig. 3C). This occurs because although motion across the wire is strongly quantized, there is a continuous contribution to the density of states that is associated with the free motion of carriers along the wire. Finally, in zero-dimensional systems (0D) like NC quantum dots, the density of states consists of sharp, discrete lines for each level of size quantization (see Fig. 3D).

Dimensionally, NRs are between zero-dimensional and one-dimensional systems. The motion of carriers across the NR is strongly quantized, but there is only weak confinement along the NR axis. The density of states contains bunches of discrete states, separated by energies determined by strong confinement across the nanorod. The structure of levels inside the bunch is determined by slow motion along the NR axes (see Fig. 3E).

Optical properties of spherical nanocrystals

The optical properties of nanoscale semiconductors are controlled by excitons, because in nanostructures one can never separate an electron and a hole photoexcited optically or injected electrically at such large distances that they do not affect each other. The effect of electron-hole Coulomb interaction on the optical spectra depends on the ratio of electron and hole confined energies, and the

Fig. 3 Density of states in various nanostructures: A—bulk 3D semiconductors; B—2D quantum wells, nanoplatelets; C—1D quantum wires, nanowires; D—0D quantum dots, nanocrystals; E—between 0D and 1D structure, nanorods.

Fig. 4 Schematic image of the wave function of an exciton confined in NCs with radius a . A—strong confinement regime. B—weak confinement regime.

strength of the electron-hole Coulomb interaction. The different geometrical shapes of nanoscale semiconductor structures strongly affect this ratio. In this chapter we don't consider physics of excitons in epitaxial quantum dots and rings, graphene and TMD (transition metal dioxide) layers. The discussion of their optical properties one can find in "Excitons in crystals" Chapter of ECMP 2nd edition.

In spherical NCs, the relationships between the confined energy and strength of Coulomb interaction can be characterized by the ratio of the exciton Bohr radius, a_B , to the NC radius a (Efros and Efros, 1982). A strong confinement regime (when the confined energy is larger than the Coulomb energy) exists if the NC radius is smaller than the exciton Bohr radius. The optical properties of such nanocrystals are determined by transitions between electron and hole quantum size levels. As a result, the absorption spectra of NCs in this limit can be written as: (Efros and Efros, 1982; Brus, 1984; Ekimov and Onushchenko, 1984)

$$\hbar\omega_{l,n} = E_g + E_e(l, n) + E_h(l, n) - 1.8 \frac{e^2}{\epsilon_s a}, \quad (6)$$

where ϵ_s is the semiconductor dielectric constant. The last term considers the electron-hole Coulomb attraction, which is calculated perturbatively. The selection rules for optically allowed transitions between electron and hole confinement levels in the strongly confined limit are controlled by the square of the overlap integral $\left| \int d^3r \psi_e(\vec{r}) \psi_h(\vec{r}) \right|^2$ between electron $\psi_e(\vec{r})$ and hole $\psi_h(\vec{r})$ wave functions (see Fig. 4A). In the parabolic band approximation, the electron and hole wave functions are identical, and due to orthogonality conditions, transitions are allowed only between levels with the same quantum levels: from 1S_h to 1S_e or from 1P_h to 1P_e levels, etc. The radiative decay rate $1/\tau$ in this limit is also proportional to the overlap integral $1/\tau = 1/\tau_0 \left| \int d^3r \psi_e(\vec{r}) \psi_h(\vec{r}) \right|^2$, where the decay time factor τ_0 is on the order of several nanoseconds in various semiconductors (Efros and Brus, 2021).

In the opposite case of a weak confinement regime (that is realized when the exciton Bohr radius (a_B) is much smaller than the NC radius ($a \gg a_B$)) the exciton binding energy is larger than the confinement energy. The optical properties in this case are determined by the spectra of confined excitons. Excitons move in a NC as hydrogen atoms move in a box (see Fig. 4B).

The size dependence of the blue shift of the lowest exciton levels is described by the “particle-in-a-box” equation that can be found in any handbook on quantum mechanics. Assuming that the NC has a spherical shape and is surrounded by infinitely high potential barriers, this gives the following expression for the size dependence of the exciton lines (Ekimov and Onushchenko, 1981; Efros and Efros, 1982):

$$\hbar\omega = E_g - E_{ex} + \frac{\hbar^2\pi^2}{2Ma^2}, \quad (7)$$

where E_g and E_{ex} are the bulk energy gap and exciton binding energy, and M is the effective mass of the exciton center of mass motion. The wave function of the confined exciton in this limit can be written as $\Psi(\vec{r}_e, \vec{r}_h) = \phi_{ex}(\vec{r})\Phi_{CM}(\vec{R})$, where $\phi_{ex}(\vec{r})$ is the wave function that describe relative motion of electron and hole within exciton, and $\Phi_{CM}(\vec{R})$ is the wave function of the exciton confined in NCs. The radiative decay rate in this case is also proportional to the overlap integral and can be written as (Efros and Efros, 1982):

$$\frac{1}{\tau} = \frac{1}{\tau_0} \left| \int d^3r \Psi(\vec{r}, \vec{r}) \right|^2 = \frac{\varphi_{ex}^2(0)}{\tau_0} \left| \int d^3R \Phi_{CM}(\vec{R}) \right|^2 \sim \frac{1}{\tau_0} \frac{a^3}{a_{ex}^3} \quad (8)$$

One can see from Eq. (8) that the ground exciton state is characterized by a giant oscillator transition strength, proportional to the cube of the NC radius, and connected with coherent exciton motion throughout the entire nanocrystal volume. This could lead to a significant shortening of the radiative decay time.

The optical spectra of excitons can be also described analytically as the range of sizes: $\frac{\epsilon_i \hbar^2}{m_e e^2} \gg a \gg \frac{\epsilon_i \hbar^2}{m_h e^2}$ which can be realized in semiconductors where the effective mass of holes is much larger than the effective mass of electrons ($m_h \gg m_e$). In this size regime, which is called intermediate confinement, the hole moves in an adiabatic static potential created by the fast motion of the strongly confined electron at the NC center (Efros and Efros, 1982; Ekimov et al., 1986). A summary of the size-dependent optical spectra for these three above-mentioned regimes in different semiconductor NCs was reported by Ekimov et al. (1985).

Let us start from the weak confinement regime. In CuCl, the bulk exciton radius is 0.7 nm, and the weak confinement regime holds in all studied NCs. Fig. 5A shows the low temperature absorption spectra of CuCl NCs measured in three different glass

Fig. 5 Size dependent absorption spectra and photoluminescence decay times of CuCl NCs. A—absorption spectra of 2, 2.9 and 31 nm radius CuCl NCs. samples with average NC radius $a = 2.0, 2.9$, and 31 nm (Ekimov and Onushchenko, 1981). All spectra exhibit two exciton lines connected with the two valence band subbands (Z_3 and $Z_{1,2}$) of CuCl. The absorption spectra of the largest 31 nm radius NCs are nearly identical to those of the bulk and both exciton lines blueshift as NC size decreases (Efros and Brus, 2021). The shift of both exciton lines plotted as a function of the inverse square of the NC radius is shown in Fig. 5B. The size dependence of the shift is linear in this scale, and for all investigated sizes is very well described by Eq. (7) (Ekimov and Onushchenko, 1981).

The ground exciton state in CuCl NCs indeed shows the giant oscillator transition strength. The giant oscillator transition strength proportional to the ratio a^3/a_{ex}^3 (see Eq. (8)) brings the radiative decay times of these NC (shown in Fig. 5C) to the sub-nanosecond range at low temperatures (Itoh et al., 1990). The solid line in Fig. 5C shows that radiative decay times are scaled as $1/a^3$ with increasing NC radius a . Recently, the sub-nanosecond radiative decay times connected with giant oscillator transition strengths of confined excitons were also measured in large perovskite NCs (Becker et al., 2018).

Detailed investigations of strong confinement regime have been conducted in CdS and CdSe NCs, where $a_B = 28$ Å and $a_B = 56$ Å, respectively. Fig. 6A shows the low-temperature absorption spectra of CdS NCs measured in four different glass samples with average NC radius $a = 1.2, 1.5, 2.3$, and 33 nm (Ekimov and Onushchenko, 1984). The red curve shows the absorption spectra of very large 33 nm radius NCs. These spectra are nearly identical to the absorption spectra of bulk CdS, and have a bulk energy gap equal to 2.5 eV. The fine structure at the band edge is created by the three excitons connected with the three valence subbands of this material. It is seen that a decrease in NC size leads to a strong shift of the absorption edge to higher energy, and is accompanied by the oscillations of interband absorption magnitude. The energy gap increases dramatically: up to 0.8 eV in the smallest NCs.

The experimental size dependence of the band edge (empty circles) and spectral positions of oscillations maxima (empty triangles and squares) measured in CdS NCs at liquid helium temperatures is connected with the size-dependent optical transitions described by Eq. (6) (shown in the cartoon in Fig. 6B). This size dependence is plotted as a function of the inverse square of the NC radius in Fig. 6C. The red lines going through these data are plotted as a guide to the eye. The dependence should be almost linear in $1/a^2$ scale in the parabolic approximation, according to Eq. (6). The deviations from linear dependence seen in Fig. 6C are connected

with the nonparabolicity of the electron energy spectra. The initial slopes of the curves that describe the absorption spectra in very large NCs (black straight lines) are in a very good agreement with Eq. (6), if one uses an electron effective mass $m_e = 0.2 m_0$ for bulk CdS, where m_0 is the free electron mass. Only electron levels are resolved in the absorption spectra. The 15% dispersion of CdS NC sizes in the samples studied in Ekimov and Onushchenko (1984) was too large to resolve the hole level structures. The spacing between hole levels is too small due to the very large hole effective mass of CdS, and dispersion completely washes this structure out.

It took 9 more years for the structure of the hole levels in CdSe NCs to be revealed, which occurred when Ekimov et al. (1993) was able to narrow the size-distribution of these NCs to 5%. Fig. 7A shows the absorption spectrum and its second derivative for CdSe NCs with mean radii 3.8, 2.6, and 2.1 nm (Ekimov et al., 1993). This observed level structure, however, cannot be described within the parabolic-band model even qualitatively, because the valence band of CdSe consists of 6 subbands, which changes both the level structure and optical selection rules. The appropriate theory, which accounts for the multiband structure of the valence band, was developed by Grigoryan et al. (1990a,b). The complete description of absorption spectra in Ekimov et al. (1993) is also required to take into account the non-parabolicity of the electron spectra. Fig. 7B shows the size dependence of the lowest electron and hole levels calculated within the 6-band effective mass model, plotted as a function of the inverse square of the NC radius. The red and blue arrows in Fig. 7B show the optically allowed transitions to the 1S and 1P electron levels. One can see that there are no selection rules connected with the main quantum number, and transitions to the lowest electron S and P levels are allowed from many hole levels having S and P angular symmetry.

Fig. 7 Size dependent absorption spectra of CdSe NCs. A—the absorption spectrum and its second derivation for CdSe nanocrystals with mean radii 3.8, 2.6, and 2.1 nm. Optical properties of anisotropic semiconductor nanostructures

After the first 20 years of research (20 years ago), the electronic and optical properties of spherical NCs were very well understood (Efros and Brus, 2021). Even the first report on NC shape control and the growth of NRs by Peng et al. (2000) has showed, however, that NR optical properties differ significantly from those of spherical NCs. An even more dramatic change of these properties was reported for NPLs grown 8 years later by Ithurria and Dubertret (2008). For example, even the first grown NRs and NPLs showed high PL quantum yields (Peng et al., 2000; Bouet et al., 2013; Ithurria et al., 2011). Nonradiative Auger recombination is suppressed (Htoon et al., 2003a,b; She et al., 2014; Kunneman et al., 2013) and consequently, NRs and NPLs show low-threshold stimulated emission (Kazes et al., 2002; Htoon et al., 2003a,b; She et al., 2014; Grim et al., 2014). NR photoluminescence is nearly 100% linear polarized (Hu et al., 2001; Shabaev and Efros, 2004). Photoluminescence of NPLs show very narrow PL linewidths and sub-nanosecond decay times (Tessier et al., 2012; Biadala et al., 2014).

The exciting optical properties of NRs and NPLs clearly indicate that they will be important building blocks in future nanotechnology and may replace spherical NCs in biological labeling, lasing applications, and solar energy harvesting applications. So what is the source of the improved properties of NRs and NPLs, and how can we control them? I will show below that most of these improved optical properties are related to the spectra of one-dimensional excitons in NRs and two-dimensional excitons in NPLs that control the PL of these anisotropic structures.

The strong anisotropy of the nanostructure shape leads to the spatial confinement anisotropy of the electron and hole energy spectra (which is discussed above) and anisotropy of dielectric confinement. Both of these effects play an important role in exciton creation and exciton properties, and allow for independent control of NR and NPL optical properties. The effect of spatial confinement anisotropy was discussed above, so let us consider the effect of dielectric confinement connected with small dielectric constant of the media surrounding the nanostructures.

Effect of dielectric confinement on electron-hole energy spectra

Now let us discuss how the difference in dielectric constant of semiconductors and their surrounding media affect the electron-hole spectra in anisotropic nanoscale semiconductor structures such as NRs, NPLs, or nanowires. The charge near the surface that separates two media with different dielectric constants creates media polarization. For a flat surface, this polarization can be described by an image charge positioned at some distance from the surface, and whose value is proportional to the difference in dielectric constants. This image charge creates a force acting on the original charge—the so-called “mirror force.” If the dielectric constant of the external media is smaller than the dielectric constant of internal media, the “mirror force” is repulsive. This leads also to a repulsive potential that pushes the electron away from the surface (see Fig. 8A).

In nano-scale semiconductors surrounded by media with a smaller dielectric constant, this repulsive potential increases the energy of the electron and hole quantum size levels. In the diagram, shown in Fig. 6B the dashed line shows the quantum size level in the absence of the dielectric confinement effect. The repulsive electrostatic potential connected with the mirror force decreases the depth of the quantum well, and increases the energy of the quantum size level.

Now let us consider the effect of dielectric confinement on the electron-hole Coulomb interaction. Although electrons and holes are confined in NRs, NPLs or nanowires, the electric field of their charge distribution is not confined within the rod, and penetrates into the surrounding medium as it is shown in Fig. 8C. The dielectric constant of this medium is significantly smaller than in the semiconductor. This enhances significantly the “e-h” Coulomb interaction.

This effect is practically non-existent in NCs, because electron and hole charge distributions are almost identical in spherical NCs, and they compensate each other at each point of the NC. The NC retains its local neutrality even after exciton creation (see Fig. 8B). If there is no charge in the NC, there is no electric field outside of the nanocrystal. This is not the case for NRs, NPLs and nanowires and the electron-hole interaction at a distance larger than their thickness is characterized by the external (small) dielectric constant, ϵ_m .

The enhanced “e-h” Coulomb interaction in all these nanostructures can be written in the following form,

$$U(\vec{r}_e, \vec{r}_h) = -\frac{e^2}{\epsilon_s |\vec{r}_e - \vec{r}_h|} - eV_s(\vec{r}_e, \vec{r}_h) + \frac{e}{2}V_s(\vec{r}_e, \vec{r}_e) + \frac{e}{2}V_s(\vec{r}_h, \vec{r}_h), \quad (9)$$

where the first term is the direct “e-h” interaction in the semiconductor, the second term is the “e-h” Coulomb interaction mediated by the difference in dielectric constants of a semiconductor and the surrounding media, and the last two terms are the self-interaction of electrons and holes, each with its own image, which take mirror forces into account.

The enhancement of the Coulomb interaction in thin semiconductor films was first calculated by Ritova (1967). Later, her results were independently reproduced by Keldysh (1979) who gave the following analytical expression which describes this interaction:

$$V(\rho, z_e, z_h) = -\frac{4\pi e^2}{\epsilon_s} \int \frac{d^2k}{(2\pi)^2} e^{2ik\rho} \frac{ch[|k|(\frac{d}{2}-z_e) + \eta]ch[|k|(\frac{d}{2}-z_h) + \eta]}{|k|sh[|k| + 2\eta]} \quad (10)$$

where $\rho = (x_e - x_h) + (y_e - y_h)$ is the distance between an electron and a hole in the film plane, z_e and z_h are the electron and hole coordinates in the direction perpendicular to the film plane, d is the film thickness and $\eta = 0.5 \ln [(\epsilon_s + \epsilon_m)/(\epsilon_s - \epsilon_m)]$.

Fig. 8 Effect of difference of dielectric constant and surrounding media. A—Potential created by the image charge pushes an electron from the surface. B—Cartoon that shows that the mirror force potential in a semiconductor nanostructure embedded in media with a small dielectric constant, resulting in the shift of the carrier-confined level to a higher energy—this is the dielectric confinement effect. C—The enhancement of the Coulomb interaction due to penetration of the electric field of carriers confined in nanoplatelets and nanorods in the surrounding media. D—Absence of the Coulomb enhancement in spherical NCs due to local compensation of electron and hole charges at each point in the NC. Reproduced with permission from Efros AL and Brus LE (2021) Nanocrystal quantum dots: From discovery to modern development *ACS Nano* 15: 6192–6210. Copyright 2021 American Chemical Society.

When the distance between the electron and hole is smaller than the film thickness d , the Keldish-Ritova Coulomb potential describes the three-dimensional attraction between the electron and hole $-e^2/\epsilon_s r$, with dielectric constant of semiconductors, where $r = \sqrt{\rho^2 + |z_e - z_h|^2}$. At the largest distances when $\rho \gg (\epsilon_s/\epsilon_m)d$ it has the form of a 2D Coulomb interaction— $e^2/\epsilon_m \rho$ with the smaller dielectric constant of surrounding media, ϵ_m . At intermediate distances, $d < \rho < (\epsilon_s/\epsilon_m)d$, the attractive Coulomb potential has a weak logarithmic dependence on the distance $\sim \ln[(\epsilon_s/\epsilon_m)(d/\rho)]$, that provides a slow transition from one law to the other.

The self-interaction potentials for electrons $\frac{e}{2} V_s(\vec{r}_e, \vec{r}_e)$ and holes $\frac{e}{2} V_s(\vec{r}_h, \vec{r}_h)$ in films can be obtained from the electron-hole Coulomb potential described by Eq. (10) (Botao et al., 2020):

$$\frac{e}{2} V_s(z, z) = -\frac{1}{2} \left[V(\vec{r}_e, z_e, z_h) + \frac{e^2}{\epsilon_s |\vec{r}_e - \vec{r}_h|} \right]_{\vec{r}_e \rightarrow \vec{r}_h} \quad (11)$$

In addition to films, the analytical form of enhanced electron-hole Coulomb interaction was found for bodies with high symmetry such as: balls, ellipsoids and cylinders, see, for example, Batygin and Topygin (1965), and Smythe (1950) correspondingly. The corresponding expressions were used for calculations of the exciton spectra in NCs by Grigoryan et al. (1990a,b) and CdSe (Shabaev and Efros, 2004) and PbSe (Bartnik et al., 2010) NRs by and CdSe (Benchamekh et al., 2014) and CsPbBr₃ (Gramlich et al., 2021) NPLs.

Two dimensional excitons in nanoplatelets

Let us discuss the optical properties of NPLs. Fig. 9A shows the TEM images of CdSe NPLs reported in Ithurria and Dubertret (2008). You can see that the lateral size of these structures is on the order of 10–20 nms. The well-defined thicknesses of these NPLs vary in a controlled manner, from 2 to 10 monolayers. This was shown using transmission electron microscopy and optical spectroscopy.

Fig. 9B shows the absorption and the emission spectra of CdSe NPLs with four different thicknesses (Ithurria et al., 2011). The number of CdSe monolayers for these samples is shown here: 5, 4, 3 and 2. You see that the two absorption lines shift to blue by nearly 1.2 eV from that of the bulk energy gap of CdSe (equal to 1.8 eV). These NPLs have electronic properties of quantum wells. The absorption spectra display two well-resolved transitions that correspond to the electron-heavy hole transition (lowest energy) and to the electron-light hole transition (highest energy).
